This condition is especially serious because the circulatory tissues are poorly equipped for combating infection. Whereas other tissues of the body may literally wall up an infection so that it can be destroyed by the white cells, the heart and arterial tissues have no such ability to isolate an infection. A large percentage of persons who have bacterial endocarditis have had a previous heart disability. The heart may have some congenital structural defect, or the endocarditis may have resulted from a disease of the heart, such as rheumatic fever. Affected persons usually are young adults, although the disease may attack any age group.

One of the most characteristic signs of bacterial endocarditis is fever, always present in the acute form, but persons with the subacute form may suffer only intermittent fever. The onset of the fever is almost always a result of the presence of free bacteria in the blood stream. The physician may withdraw a sample of blood during a *febrile* period for culture of the organism. The patient also suffers from anemia, which is partly caused by the destruction of red blood cells by the bacteria.

Embolism is also a complication of bacterial endocarditis. Emboli that develop because of the disease may cause *Osler's nodes* in the skin. These are small, raised, reddened areas found most often on the inside of the fingers and toes. They may be somewhat tender, but usually disappear within a few days. Larger and much more painful lumps may appear on the limbs, beneath the skin; usually they remain about a week. Sometimes these are caused by hemorrhage.

When a bacterial embolus lodges within an artery, it may cause a bulging sac from the wall of the artery called a *mycotic aneurysm*. These aneurysms appear in the smaller arteries, such as those that supply the skin. However, they may occur elsewhere.

When emboli become lodged within the blood vessels of the lungs, they produce symptoms similar to those of *hemorrhagic bronchopneumonia*. Emboli affecting the kidneys will cause many of the signs and symptoms of kidney malfunction, but rarely cause *fatal nephritis*. An embolus lodging in the brain may result in widespread damage to nervous tissue by cutting off the blood supply to nerve centers. Probably because of toxins manufactured by the bacteria, the smaller blood vessels (the capillaries) often become unusually fragile. The rupture of the walls of these tiny vessels causes a hemorrhage; the resulting symptoms depend upon the location of the capillaries affected. When capillaries in the skin are affected by the toxins, numerous small, purplish spots appear in the skin. They may be seen almost anywhere in the skin or mucous membrane. When they appear under the nails, the spots often resemble splinters. There may be capillary ruptures on the surface of internal organs, notably the heart and kidneys. In addition to these signs, the spleen usually becomes enlarged and may feel tender to the touch.

All individuals suffering from bacterial endocarditis may not exhibit all of the foregoing symptoms and signs. An individual having an infection of the right side of the heart might well exhibit signs in the lungs, since they are supplied with blood by the right side of the heart. Conversely, an individual who has an infection of the left side of the heart, the aorta, or the mitral valve, will be more likely to have systemic symptoms — emboli in the skin and organs, kidney involvement, enlargement of the spleen, and aneurysms.

In almost all cases, the infection can be controlled by one more of the various antibiotic drugs. However, the dosages must be large and prolonged to insure that the drugs destroy the bacteria. The usual period for antibiotic administration is about one month. In most cases, blood tests will show that the bacteria are resistant to one or more types of antibiotic, so that the treatment may be even longer.

Kidney malfunction caused by bacterial endocarditis may be permanent, restricting the patient to reduced activity.

The individual with chronic heart disease should discuss this with the dentist or surgeon before undergoing tooth extraction, or simple ear, nose, or throat operations. These procedures may be especially dangerous, since bacteria from a throat infection or tooth abscess enter the blood stream in large numbers and, consequently, infect damaged areas of the heart.

ENDOCRINE SYSTEM. The endocrine system is made up of several organs situated in various parts of the body, all of which are characterized by their ability to produce active chemical substances called *hormones*. The organs of the endocrine system are called *glands of internal secretion* because they secrete the products of their activities directly into the blood stream for distribution throughout the body. *Endocrinology* is the science of the ductless glands and an *endocrinologist* is one who specializes in the science of the ductless glands and their function.

As indicated in Fig. 1, the endocrine glands are: (1) the *pituitary*, located at the base of the brain, which manufactures hormones that act as growth-stimulators of children, assist in the process of sexual maturation, and assist in the coordination of the activity of other endocrine glands, is thus sometimes referred to as the "master gland" — therefore, disorders of the pituitary can have grave significance; (2) the *hypothalamus*, which is part of the diencephalon, the central portion of the brain, and which is concerned with the regulation of many autonomic functions, including body temperature, sleep, behavior, appetite, and emotional response; (3) the *thyroid*, which is located in the neck, and which regulates the general speed of most of the chemical reactions in the cells of the body, regulating the calcium level in the blood, and playing a role in growth, development, and metabolism; (4) the *parathyroids*, located adjacent to the thyroid gland in the lower front portion of the neck and which maintain normal concentrations of calcium in many of the body tissues; (5) the *gonads* (*testes* in the male; *ovaries* in the female), which are the fundamental organs of reproduction and which produce gonadal hormones (respectively male and female hormones) that set secondary sex characteristics; (6) the *adrenals*, sometimes referred to in humans as the *suprarenal glands*, located near the top of the kidneys, and which secrete numerous hormones, notably *adrenalin* (epinephrine), which increases blood pressure, speeds up the respiration and the heartbeat, augments the amount of sugar in the blood, and in stressful situations, gives the individual a feeling of added strength and aggressiveness; (7) the *thymus*, which lies just above the heart, and which plays a central role

Fig. 1. Distribution of the major endocrine glands in the human body.

in establishing the immunological capacities of the body, producing a hormone which is responsible for the production of cells with the capacity to make antibodies and reject foreign elements; (8) a part of the *pancreas*, notably the *islets of Langerhans* (see also **Diabetes Mellitus**), which secrete insulin, glucagon, and gastrin, important in the regulation of sugar levels in the blood; and (9) sometimes classified as part of the endocrine system, the *pineal gland*, a small gland attached to the posterior part of the brain, behind and above the third ventricle, the functions of which remain somewhat obscure, but which secretes a hormone known as melatonin, an agent affecting pigment cells. Additionally, the *placenta* (the spongy structure in the uterus through which the fetus is nourished) also secretes hormones and thus is closely related to the endocrine system, and functional during pregnancy.

Some endocrine glands also perform other activities. For example, the pancreas produces a digestive secretion that is passed into the small intestine through a system of ducts.

Hormones fall into two general categories: (1) *messengers*, and (2) *managers* — to use a simple analogy. Most of the endocrine glands produce one or more of each type. The messengers are those hormones that act upon tissues and organs outside of the endocrine system to speed or slow their normal functions. The managers also carry messages, but always within the endocrine system. They are responsible for the fact that some endocrine actions occur constantly, some occur periodically, some during certain years only, and some occur only once during the life of the individual.

One of the principal functions of the nervous system is to correlate all the parts of the body so that they may function harmoniously as a unit. In achieving this harmony, the nervous system is supplemented by the endocrine system; the two systems mutually affect each other. Mental strain, fear, anger, or any emotional state affects the activities of the endocrine glands. A well-known action is the accelerated production of adrenalin during a state of rage or fear. More subtle changes occur constantly in the endocrine system, elicited by some form of nervous stimulation. In some instances, the changes in endocrine activity are reflected in perceptible acts; in others, they remain imperceptible. The crying spells, hot flashes, and irritability sometimes seen in women during premenstrual tension or menopause illustrate this point.

The hypothalamus is part of both the nervous system and the endocrine system. The nerves connecting it to the pituitary as well as to the centers of neurosecretion permit a direction and indirect influence by the nervous system upon its endocrine counterpart. This influence is all the greater because the pituitary, in turn, has a definite influence over other endocrine glands. The hypothalamus also produces hormones which stimulate and which inhibit the pituitary gland. See **Nervous System and the Brain**.

ENDODERM. See **Embryo**.

ENDODERMIS. The central cylinder of roots is separated from the cortex by the endodermis, which is a tissue composed of a single layer of cells. Since its first description by Caspary [1866], the root endodermis and its structure and function have been the object of much speculation. Because of the characteristic cell wall modifications in the radial walls (Casparian bands) of the endodermis (Figure 1), it was argued that the endodermis should form a perfect apoplastic barrier for water and solvents radially diffusing from the soil solution across the cortex to the central cylinder of roots, where xylem vessels are located. However, recent results, based on investigation of the chemical composition and transport properties of endodermal cell walls, indicate that there can be a substantial apoplastic bypass across Casparian bands. In addition to its function as a transport barrier, the endodermal cell wall, and also the hypodermal cell wall, of roots form an important barrier against invading microorganisms.

Anatomy

In root cross-sections a pronounced modification of the radial endodermal cell walls occurs that can be made visible by fluorescence microscopy (Figure 1). Due to the deposition of phenolic compounds showing a strong autofluorescence, endodermal cell walls are chemically different from normal plant cell walls, which are mainly composed of carbohydrates. Anatomically, three developmental states can be distinguished. In its primary developmental state, the endodermal cell wall is characterized by the deposition of Casparian bands on the radial cell walls. In many species, a secondary development state (deposition of a lipophilic suberin lamella

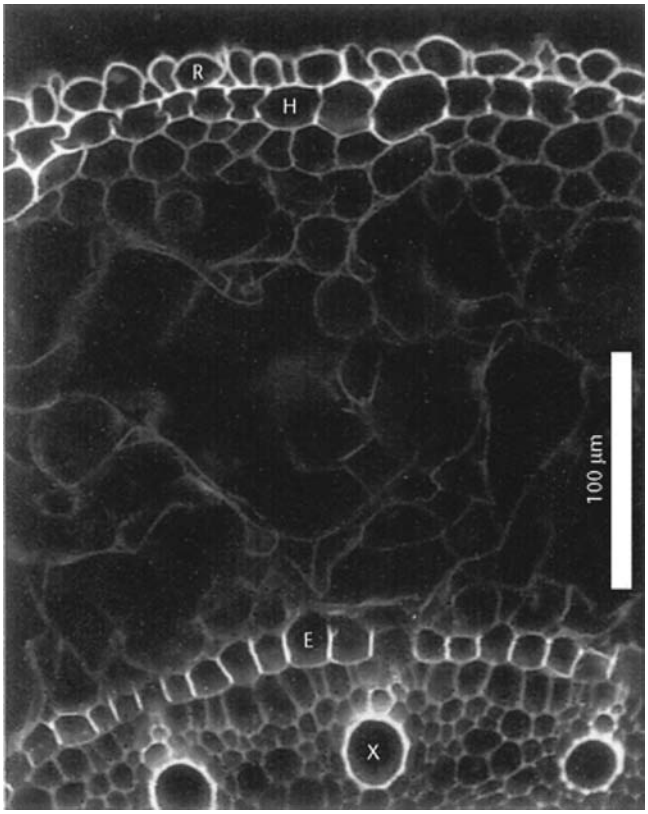

Fig. 1. C Section across a primary root of maize (*Zea mays* L.). Lignified and suberized cell walls (R, rhizodermal cell layer; H, hypodermal cell layer; E, endodermal cell layer; and X, xylem vessel) exhibit a bright autofluorescence (excitation light used: 395–440 nm). Bar, 100 µm. (Illustration courtesy of K. Hartmann and L. Schreiber

on the inner surface of the primary cell wall) and a tertiary developmental state (deposition of U-shaped cell wall thickenings onto the radial and inner tangential cell walls of the endodermal cells) can be observed. Casparian bands as well as suberin lamellae have also been detected in the root hypodermis of many species [Wilson and Peterson, 1983]. Furthermore, there are some indications that an endodermis with a Casparian band can also occur in stems and leaves [Lersten, 1997]. The physiological function in stems and leaves, however, remained basically unknown until recently, when it was reported that the shoot endodermis is responsible for the perception of gravity [Fukaki et al., 1998]. See also **Plant Anatomy**.

Isolation and Chemical Composition

If root sections are treated with a mixture of cell wall degrading enzymes (pectinases and cellulases), cell walls that are chemically different from normal carbohydrate walls will resist the enzymatic attack. Using this approach it has become possible to isolate highly purified samples of endodermal and hypodermal cell walls [Karahara and Shibaoka, 1992; Schreiber et al., 1994], which can be further used for the analysis of the chemical composition. After chemical degradation of isolated cell wall samples, the monomer composition of the biopolymers can be determined by modern analytical techniques such as gas chromatography and mass spectrometry. Endodermal cell walls as well as hypodermal cell walls were shown to be composed of a complex mixture of different compounds. Besides normal carbohydrates, further structural biopolymers such as suberin, lignin and proteins contribute significantly to the dry mass of the isolated cell wall samples [Zeier and Schreiber, 1998; Zeier, et al.: 1999].

Endodermal cell walls in their primary developmental state (Casparian bands) contained only traces of suberin and significantly larger amounts of lignin, whereas endodermal cell walls in their secondary developmental state were characterized by a significantly larger amount of the lipophilic biopolymer suberin. Finally, tertiary endodermal cell walls were basically characterized by the deposition of lignified cellulose walls onto the suberin lamella. The chemical composition of hypodermal root cell walls was also characterized by the occurrence of suberin and lignin.

Function as Apoplastic Barrier

Endodermal as well as hypodermal cell walls have an important function as apoplastic barriers in the roots of higher plants. Due to the complicated mixture of four different biopolymers simultaneously occurring within the same cell wall, it can be postulated that these cell wall structures will form a significant barrier to microorganisms. Cell wall degrading enzymes, which are normally secreted by pathogens trying to infect plant tissues, will not easily degrade endodermal cell walls. See also **Phytopathology**.

Radial transport of water and solutes across corn (*Zea mays* L.) roots has been measured using root pressure probes [Peterson et al., 1993; Steudle, et al.:1993]. Radial water flow across roots with primary endodermal cell walls (Casparian bands) was not increased when the endodermis was damaged by puncturing, indicating the endodermis did not represent a major barrier towards the flow of water. However, solute permeability of sodium chloride was significantly increased when the root endodermis was punctured, which proved that the endodermis represented an important apoplastic barrier for the radial transport of solutes. This confirmed earlier works where it was also shown, using tracers and electron microscopy, that the endodermis formed an apoplastic barrier [Du Pont and Leonard, 1977; Robards and Robb, 1974]. Recent results on the radial hydraulic conductivity of roots indicated that the formation of an exodermis (root hypodermis with Casparian bands) can also contribute significantly to the radial resistance of plant roots towards water transport [Zimmermann, et al., 2000]. However, there is also substantial evidence that the radial transport of organic molecules, such as the phytohormone abscisic acid, can have a significant apoplastic component [Freundl, et al.: 1998]. Thus, it must be concluded that apoplastic barriers in roots (endodermal and hypodermal cell walls) are by no means perfect barriers completely impermeable for water and dissolved ions and organic molecules. Depending on the developmental state and the differentiation of endo- and hypodermal cell walls and on the physico-chemical properties of the substances, properties of the apoplastic barrier in roots can vary and an apoplastic bypass may significantly contribute to the radial transport in roots.

Development and Root Mutants

The genetics of root development and formation of the endodermis with Casparian bands has been analyzed using *Arabidopsis thaliana*, which is a good model system due to its simple cellular organization. Initials deriving from the root meristem give rise to specific cell types resulting in the final radial organization of plant roots. Analysis of cell lineages and pattern formation has indicated that cortical and endodermal cells are derived from the same initial. Different mutations leading to characteristic changes in the radial organization of roots have been characterized. In SHORTROOT mutants the endodermis is completely missing, whereas in SCARECROW mutants there is no segregation between endodermis and cortex cells [Scheres, et al.:1995]. It is postulated that the SHORTROOT gene controls the number of cell layers in the root cortex.

Recently, shoot gravitropism mutants have been isolated, and it was found that the endodermis in shoots is responsible for the negative gravitropism of *Arabidopsis thaliana*. Most interestingly, the genes responsible for the shoot gravitropism have been found to be allelic to the shortroot and scarecrow genes involved in the formation of the root endodermis. Thus, the same genes seem to be involved in the radial pattern formation of roots as in shoots of *Arabidopsis*. See also **Shoots and Buds**.

ENDOGENIC. A term used by geologists to denote processes originating within the earth.

ENDOGENOUS. Originating and developing from within — without influence of external factors and stimuli. In medical usage, a disorder, frequently of a biochemical nature, which arises "naturally" from and within a cell or organ in the absence of external contributing factors. Such malfunctions may arise from genetic abnormalities that are present with an individual entity and require no stimuli to generate symptoms of their presence with the exception of the passage of time.

ENDOMORPHISM. That phase of contact metamorphism that takes place in the intrusive magma rather than in the walls of the rock mass which it invades.

ENDOSCOPE. An instrument equipped with a lighting and lens system used for visual examination of the interior of a body organ or cavity.

ENDOSMOSIS. A type of osmosis in which the solvent dialyzes into the system. Exosmosis is the reverse process. The two processes may be illustrated by the conditions in the living cell; when the plasma is hypertonic, solvent passes from the cell into the plasma (exosmosis); when the plasma is hypotonic the solvent passes from the plasma into the cell (endosmosis).

The movement of the liquid relative to colloidal particles under an applied electrical field is termed electro-endosmosis.

See also **Ocean Resources (Energy)**.

ENDOTHELIUM. The delicate lining of the organs of circulation. It is one cell in thickness and is continuous throughout the closed passages with the exception of the sinusoids. The walls of capillaries are made up of little more than the endothelium.

END POINT (Chemical Reaction). See **Chemical Reaction Rate**.

END-STAGE RENAL DISEASE (ESRD). See **Kidney and Urinary Tract**.

ENERGY. In most contemporary texts and those of the last several decades, energy generally has been defined simply as "the ability or capacity to do work." This is a broadening of the earlier definition in terms of Newtonian mechanics, which was "a property of moving masses."

The concept of energy is central to thermodynamics, quantitative chemistry, and electromagnetism. Consider Einstein's mass-energy equation, $E = mc^2$ for the interconversion of mass and energy, where $E =$ energy in ergs; $m =$ mass in grams; and c is the velocity of light in centimeters per second. Or, Planck's equation, which expresses the fundamental law of quantum theory, stating that the energy transfers associated with radiation are made up of definite quanta of energy proportional to the frequency of the radiation: $E = h\upsilon$, where $E =$ the value of the quantum units of energy; $\upsilon =$ the frequency of radiation; and h is the elementary quantum of action, more commonly known as Planck's constant (6.6256×10^{-27} erg-second — the proportionality factor that, when multiplied by the frequency of a photon, gives the energy of the photon).

Although the fundamental definition of energy can be brief, it immediately calls for an explanation of work, and of power. In the strict physical sense, work is performed only when a force is exerted on a body while the body moves at the same time in such a way that the force has a component in the direction of motion. The amount of work done during motion from point "a" to point "b" can be expressed by

$$W = \int_a^b F \cos\theta \; ds$$

where F is the total force exerted and θ is the angle between the direction of F and the direction of the elemental displacement, ds. In the cgs system, the unit of work is the *dyne-centimeter* or *erg*; in the mks system, the *newton-meter* or *joule*; and in the English system, the *foot-pound*.

In rotational motion, the definition just given can be exactly applied, but it is often convenient to express the force as a torque and the motion as an angular displacement. The work done will be

$$W = \int_a^b \tau \cos\theta \; d\omega$$

where in this case, θ is always the angle between the torque τ, expressed as a vector quantity and the elemental angular motion $d\omega$, also expressed as a vector. The units of work performed in angular motion will, of course, be the same as in the case of linear motion. Notice that the definition of work involves no time element.

Power is defined as the rate at which work is performed. The average power accomplished by an agent during a given period of time is equal to the total work performed by the agent during the period, divided by the length of the time interval. The instantaneous power can be expressed simply as

$$P = dW/dt$$

In the cgs system, power has the units of *ergs per second*; in the mks system, units of *joules per second* (or *watts*); and in the English system, units of *foot-pounds per second*. A common engineering unit is the *horsepower*, defined as 550 foot-pounds per second; or 33,000 foot-pounds per minute. The SI unit of power is the watt. 1 watt = 1 joule per second. (1 joule is the work done by 1 newton acting through a distance of 1 meter.) 1 joule = 1 watt-second = 10^7ergs = 10^7 dyne-centimeters. The SI unit of force is the newton. (1 newton = 10^5 dynes). See also entry on **Units and Standards**.

Now, returning to the basic definition of energy as the capacity for performing work. This definition may be better understood when stated as: "The energy is that which diminishes when work is done by an amount equal to the work so done." The units of energy are identical with the units of work previously given.

Energy can exist in a variety of forms, some more recognizable as being capable of performing work than others. Forms in which the energy

is not dependent upon mechanical motion are generally referred to as forms of *potential energy*. The most common example in this category is gravitational potential energy. A body near the earth's surface undergoes a change in potential energy when it is changed in elevation, the amount being equal to the product of the weight of the body and the change in elevation.

Potential energy also may be stored in an elastic body, such as a spring or a container of compressed gas. It may exist in the form of chemical potential energy, as measured by the amount of energy made available when given substances react chemically. Potential energy also exists in the nuclei of atoms and can be released by certain nuclear rearrangements.

Kinetic energy is the energy associated with mechanical motion of bodies. It is quantitatively equal to $\frac{1}{2}mv^2$, where m is the mass of a body moving with velocity v. In the case of rotational motion, the kinetic energy is more easily calculated, using the expression $\frac{1}{2}\mathrm{I}\omega^2$, where I is the moment of inertia of the body about its axis of rotation and w is the angular velocity. Kinetic energy, like all forms of energy, is a scalar quantity (having magnitude but not direction). In a system made up of an assembly of particles, such as a given volume of gas, the total kinetic energy is equal to the sum of the kinetic energies of all the molecules contained in the volume. Calculation of the energy of such systems is very successfully treated theoretically on the basis of statistical averages.

Within a given system, energy may be transformed back and forth from one form to another, without changing the total energy of the system. A simple example is the pendulum, in which the energy is periodically converted from gravitational potential energy to kinetic energy and then back to gravitational potential energy. A similar situation, but on a submicroscopic scale, occurs in solid materials where the atoms are vibrating under the effect of interatomic rather than gravitational forces. As the temperature of a solid increases, the energy associated with the vibration of the atoms increases.

The example just given illustrates how, on a macroscopic scale, heat can be considered a form of energy. Regardless of the material involved, any amount of heat absorbed or released may be quantitatively expressed as an amount of energy. A *gram-calorie* of heat is equivalent to 4.19 joules, and in the English system, a *British thermal unit* (Btu) is equivalent to 778 foot-pounds.

Potential energy is also present in electric and magnetic fields. The energy available in a region of electric field is equal to $E^2/8\pi$ per unit volume, where E is the electric field strength. Within a given volume, the total energy represented by the electric field is the integral of $E^2/8\pi$ over the volume. Similarly, the energy represented by a magnetic field may be independently calculated by integrating $H^2/8\pi$ over any given volume, where H represents the magnetic field strength. In the case of an electrically charged capacitor, the total energy in the electric field, and hence in the capacitor, can be shown to be $\frac{1}{2}CV^2$. Here C is the capacitance and V the electric potential to which the capacitor is charged. Similarly the total energy in the magnetic field associated with an inductor carrying an electric current is $\frac{1}{2}LI^2$, where L is the inductance and I is the current.

Electromagnetic radiation is a combination of rapidly alternating electric and magnetic fields. Energy is associated with these fields and is exchanged between the electric and magnetic forms. This energy in a quantum of electromagnetic radiation, such as light or gamma radiation, can be expressed in different ways, but is commonly expressed as $E = h\nu$, as previously mentioned.

For particulate radiation or any very rapidly moving mass, the expression previously given for the kinetic energy, $\frac{1}{2}mv^2$, is not accurate when the velocity approaches that of the velocity of light. The theory of relativity requires a correction be made, and the exact kinetic energy, T, may be calculated in terms of the mass, m_0, of light in vacuum, c, as follows:

$$T = m_0c^2\left[\left(1 - \frac{v^2}{c^2}\right)^{-1/2} - 1\right]$$

Notice that this formula may also be written:

$$T = (m - m_0)c^2$$

where m is the variable quantity $m_0(1 - (v^2/c^2))^{-1/2}$. This quantity represents the mass of the body, reducing to m_0 when v is zero, and approaching infinity as v approaches the speed of light.

This example illustrates another result of the theory of relativity, namely, the equivalence of mass and energy. Rewriting the last equation,

$$m = m_0 + \frac{T}{c^2}$$

The mass is seen to increase linearly with the kinetic energy of the body, the proportionality factor being c^2. It should be noted that even the rest mass, m_0, represents an amount of energy equal to m_0c^2. The total energy of a body of mass, m, can be generally given as:

$$E = mc^2 \quad \text{or} \quad E = m_0c^2 + T$$

In dealing with radiation, whether particulate or electromagnetic, it is customary to express energy in terms of electron volts. An electron volt is equal to the amount of work done when an electron moves through an electric field produced by a potential difference of one volt. One electron volt is equivalent to 1.60×10^{-12} erg. When charged particles, such as electrons or protons, are given kinetic energy by an accelerator, their kinetic energy is stated in terms of electron volts (eV), million electron volts (MeV), or billion electron volts (BeV).

A basic principle of physics known as the conservation of energy requires that within any closed system, the total energy must remain constant. Energy can be changed from one form to another; but the total, so long as no energy is added to or lost from the system, must be constant. In the case of the swinging pendulum, decreases in kinetic energy reappear as increases in potential energy and vice versa. Eventually, of course, the pendulum will stop due to the effect of frictional forces. At that time, all of the kinetic energy and gravitational potential energy will have been converted to heat.

In another example involving a radioactive atom, the total energy represented by the atom and the emitted radiation must be constant. If a gamma ray is emitted, the rest mass of the atom will be decreased by an amount equivalent to the sum of the energy of the gamma ray and the recoil kinetic energy of the atom, which will be very small. If a beta ray is emitted, the rest mass of the atom will be decreased by an amount equivalent to the sum of the rest mass of the emitted electron, the kinetic energy of the electron, and the recoil kinetic energy of the atom.

Entropy. In the mathematical treatment of thermodynamic processes there occurs very often a quantity, now relating energy to absolute temperature, now associated with the probability of a given distribution of momentum among molecules, and again expressing the degree in which the energy of a system has ceased to be *available energy*. Its mathematical form suggests that these are all aspects of a single physical magnitude. Application of the second law of thermodynamics leads to this conclusion: if any physical system is left to itself and allowed to distribute its energy in its own way, it always does so in a manner such that this quantity, called entropy, increases; while at the same time, the available energy of the system diminishes. This has led to the observation of a so-called "order of merit" for the various forms of energy.

With reference to Table 1, the energy usually flows from higher levels to lower levels — in a direction such that the entropy increases. Thus, cosmic microwave background radiation is defined as the ultimate heat sink, i.e., it represents the ultimate in energy degradation with no lower form in which to be converted.

TABLE 1. ENERGY FLOW AND ENTROPY

Form of Energy	Entropy Per Unit Energy
Gravitation	0
Energy of rotation	0
Energy of orbital motion	0
Nuclear reactions	10^{-6}
Internal heat of stars	10^{-3}
Sunlight	1
Chemical reactions	1–10
Terrestrial waste heat	10–100
Cosmic microwave radiation	10^4

The universe evolved by the gravitational contraction of objects of all sizes, from clusters of galaxies to planets. In considering that thermodynamics appears to favor the degradation of gravitational energy to other

forms, why is it that after an estimated 10 billion years since cosmic evolution, gravitational energy remains the predominant form? This is explained in terms of a series of phenomena that can be termed "hangups." These are, in essence: (1) The cosmos is large to the extreme; distances between objects are tremendously long; the average density is extremely low. Thus, matter cannot collapse gravitationally in a time shorter than the "free fall time." In relating free fall time (t) with density (d) with the formula, $Gdt^2 = 1$, where G is the constant in Newton's law of gravitation, it is apparent that the free fall time is extremely long. It is estimated that the time is about 100 billion years. But, since the density of our own galaxy is estimated at one million times that of the universe, more than the size hangup is required to preserve the galaxy. (2) An extended object cannot collapse gravitationally if it is spinning rapidly. The object assumes a stationary orbit revolving about the inner parts instead of collapsing. Thus, the earth has not collapsed into the sun. Other examples of the spin hangup at work include galaxies, planetary systems, double stars, and the rings of Saturn. (3) Hydrogen "burns" to form helium when it is heated and compressed. But, this thermonuclear burning releases energy, which opposes any further compression. Thus, a star with a lot of hydrogen cannot collapse gravitationally beyond a certain point until the hydrogen is burned up. It is estimated that the sun has been "stuck" on this thermonuclear hangup for 4.5 billion years and will need another 5 billion years to burn hydrogen before its gravitational contraction can be resumed. (4) Whereas a thermonuclear bomb is made mainly of heavy hydrogen, the sun contains ordinary hydrogen with only a trace of the heavy hydrogen isotopes. Whereas heavy hydrogen can burn explosively by strong nuclear reactions, ordinary hydrogen can react with itself only by the weak-interaction process. This proton-proton reaction proceeds about 10^{18} times more slowly than a strong nuclear reaction at same density and temperature. At least three fortunate circumstances contribute to the weak-interaction hangup: (a) without it, there would not have been a long-lived and stable sun; (b) the ocean would constitute an excellent thermonuclear high explosive; (c) hydrogen has survived rather than having been consumed in the initial, hot, dense phase of the evolution of the universe. (4) Because the transport of energy from the hot interior of the earth to the surface requires billions of years, the earth remains geologically active, these processes deriving their energy from the original gravitational condensation of the earth estimated as some 4 billion years ago. (5) There also is a special surface tension hangup, accounting for the survival of fissionable uranium and thorium nuclei in the earth's crust. They contain a high positive charge and excessive electrostatic energy such that they are ready to explode when triggered. However, before this can happen their surface must be stretched into a nonspherical shape. This process is opposed by an extremely powerful force of surface tension, estimated at about 10^{18} times stronger than that of a drop of water. Thus, it is estimated that fewer than one in a million of the earth's uranium nuclei fission spontaneously.

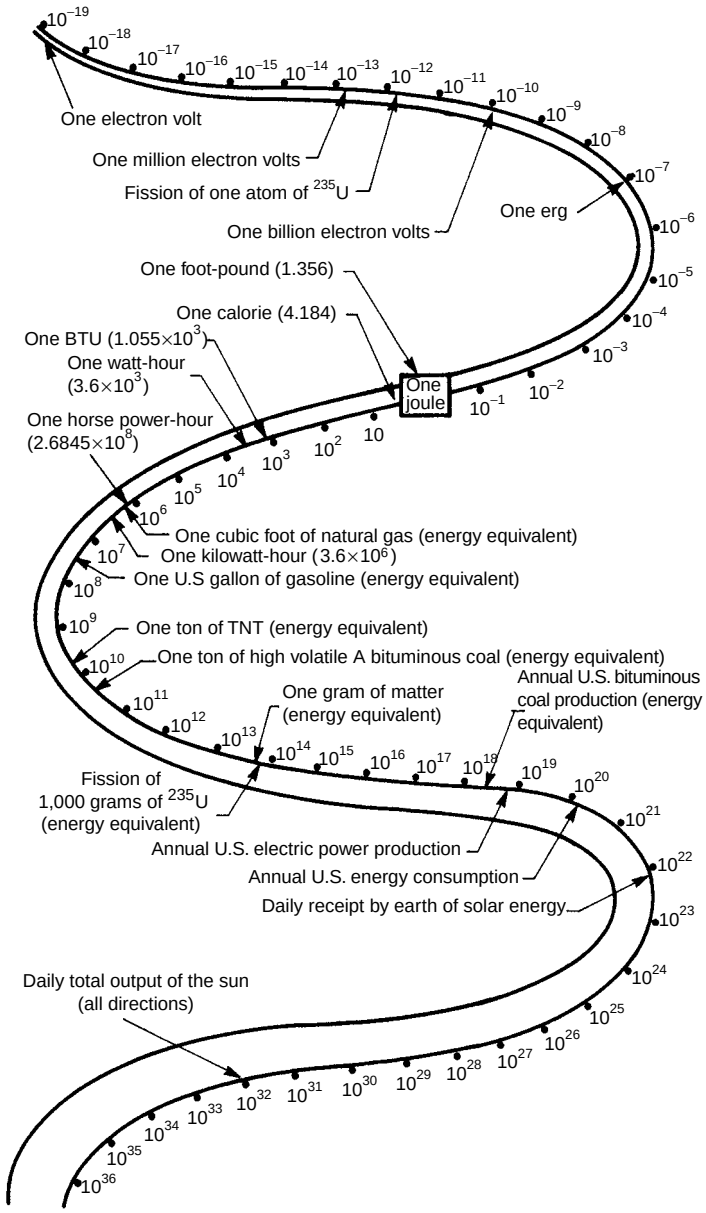

Fig. 1. Spectrum of various energy quantities. (*Source: Omnibix U.S.A.*).

Energy Technology

Breadth in the "Packaging" of Energy. In Fig. 1 a packet of energy of 1 joule (1 newton-meter) is represented by the box in the upper center. Various energy packets, ranging from 1 electron volt (10^{-19} joule) to the daily energy output of the sun (total — in all directions) of 10^{32} joules are indicated.

Perfecting contemporary energy resources and power generation and consumption and developing presently nonconventional energy resources and systems possibly pose the greatest challenge to scientists and technologists in the last quarter of this century. In particular, scientists and technologists must be encouraged to work better together in an effective and realistic fashion to create constructive solutions to the problem of the energy/environment interface.

There are numerous entries in this *Encyclopedia* on various energy topics. Consult the alphabetical index for such energy sources as coal, electric power, fuel cells, geothermal energy, hydroelectric power, hydrogen as a fuel, natural gas, nuclear power, oil shale, petroleum, solar energy, substitute natural gas and other synthetic fuels, tar sands, tidal energy, and waste materials. Also, a number of energy-converting and generating processes are described, including boilers and combustion, as well as energy-utilizing systems, such as diesel engines, gas and expansion turbines, internal combustion engines, steam engines, and steam turbines.

ENERGY BALANCE. The balance between the net warming or cooling of a volume and all possible sources and sinks of energy. The main sources and sinks of energy typically include the net fluxes of sensible heat, latent heat, and radiant energy. Conservation of energy requires that the energy received by a surface must equal that lost from the surface plus that stored. For water and land surfaces, the main source of energy is net radiation, which equals the sum of short and long waveband radiation downward minus radiation reflected or emitted upward. This energy is normally transferred into the soil (soil heat flux), into the air (sensible heat flux), or into latent heat flux (evapotranspiration or ET). Small amounts of the incoming energy can change the heat content of water or crops at the surface or are converted to other forms of energy (e.g., photosynthesis). Energy balance is often used to estimate evapotranspiration by 1) measuring net radiation, soil heat flux, and sensible heat flux; 2) entering those values into an energy balance equation; and 3) solving for the latent heat flux (ET). Under hot, dry, windy (advection) conditions, heat from the air in addition to net radiation is sometimes available at an underlying cool surface. Advection can potentially increase evaporation rates to higher than the energy available from net radiation alone.

ENERGY LEVEL. A stationary state of energy of any physical system. The existence of many stable, or quasi-stable, states, in which the energy of the system stays constant for some reasonable length of time, is an essential characteristic of quantum-mechanical systems, and is the basis of large areas of modern physics.

ENERGY (Nuclear). See **Nuclear Power Technology**.

ENERGY (Solar). See **Solar Energy**.

ENERGY STATE TERMS. Terms designating the discrete energy states of a particle in a system. Thus the energy states of an atom are called $S, P, D, F, \ldots$ terms, respectively, corresponding to the values $0, 1, 2, 3, \ldots$ of L, the resultant angular momentum quantum number of the atom. The energy states of a molecule are called $\mathbf{\Sigma}, \mathbf{\Pi}, \Delta, \mathbf{\Phi}, \ldots$ terms, respectively, corresponding to the values $0, 2, 3, \ldots$ of λ, the electronic orbital angular momentum (about internuclear axis) quantum number.

The letters indicating the value of L are usually preceded by a superscript denoting the multiplicity and followed by a subscript denoting the total angular momentum quantum number J. In addition, the principal quantum number is often written as a coefficient. Energy state terms and their transitions are shown in energy level diagrams.

Magnetic Energy State. A magnetic dipole of a moment μ in a magnetic field of flux density B has an energy that depends on orientation, $E = -\mu B \cos\theta$, or in vector notation $E = -\boldsymbol{\mu} \cdot \mathbf{B}$, in mksa units ($-\mu \cdot \mathbf{H}$ in emu). In atomic and nuclear systems the orientation of $\boldsymbol{\mu}$ relative to $\mathbf{B}$ is quantized, only certain values of $\cos\theta$ being allowed. Transitions between these allowed magnetic energy states may take place with the emission or absorption of electromagnetic (magnetic dipole) radiation of frequency given by the Bohr condition:

$$\mathrm{v} = \Delta E/h, \quad \text{or} \quad \omega = \Delta E/h$$

Particles such as electrons, protons, nuclei, etc., have intrinsic magnetic moments $\boldsymbol{\mu} = egh\mathbf{I}/2M$, where $\mathbf{I}h$ is the spin angular momentum, g the g-factor of the particle, and M is the mass of the electron or the mass of the proton. The magnetic energy states are thus given by $E = -heg\mathbf{I} \cdot \mathbf{B}/2M = -hegmB/2M$. Here m is the magnetic quantum number, which can take on the values $-I, -(I-1), \ldots (I-1), I$ where I is the spin quantum number ($\frac{1}{2}$ for electrons and protons). The energy is also often written $E = -\mu_B gmB$ or $-\mu_N gmB$ where μ_B and μ_N are the Bohr magneton and nuclear magneton respectively. The magnetic quantum number can only change by ± 1 as a result of the emission of radiation, so that there is only one emission or absorption frequency $\omega = egB/2M$.

Negative Energy State. 1. Any bound state, in which the sum of the kinetic energy and the potential energy, the latter reckoned relative to zero at infinity, is less than zero. The existence of such states is essential for the stability of any system that is not surrounded by a region of positive potential energy, such as the Coulomb barrier.

2. A consequence of the Dirac electron theory is that there exist electron states of negative total energy (including both rest mass energy and kinetic energy). Electrons in such states of negative energy are unobservable, only electrons of positive total energy being observable. The allowed positive and negative states are shown in the diagram (only $E > m_0c^2$ and $E < -m_0c^2$ are allowed in a field-free region). If a γ-ray photon of energy greater than $2m_0c^2$ (where m_0 is the rest mass energy of the electron) is absorbed by an electron of negative energy, it will be lifted into a positive energy state and will become observable. The positron is identified with the hole that is left behind.

ENERGY UNITS. See **Units and Standards**.

ENGINE. In common usage, the term engine is used widely for devices that produce motion. In stricter technical sense, an engine is said to transform energy, especially heat energy, into mechanical work. Among the prime movers, those in which the power originates in a piston and cylinder are classed as engines, while those with purely rotative motion are known as turbines.

ENKEPHALINS AND ENDORPHINS. During the past decade of brain research, the number of chemical-messenger systems identified has increased dramatically. This advance is highlighted by the discovery of a large family of brain chemicals known as *neuropeptides*. As shown by Fig. 1, these molecules are made up of long chains of amino acids, ranging from a few to as many as 39 amino acids. Research indicates that these substances are resident within the neutrons. A few of these substances, such as corticotropin (ACTH) and vasopressin, have been known for many years and identified with the hypothalamus and pituitary gland. Probably of greatest interest to researchers have been the *enkephalins* and *endorphins*. These chemicals are strikingly similar to the opiate morphine.

Identification of these substances followed the finding that specific regions of the brain possess receptor sites that bind opiates with a high affinity. These sites were revealed through the use of radioactively labeled opiate compounds. Further research showed that opiate receptors are

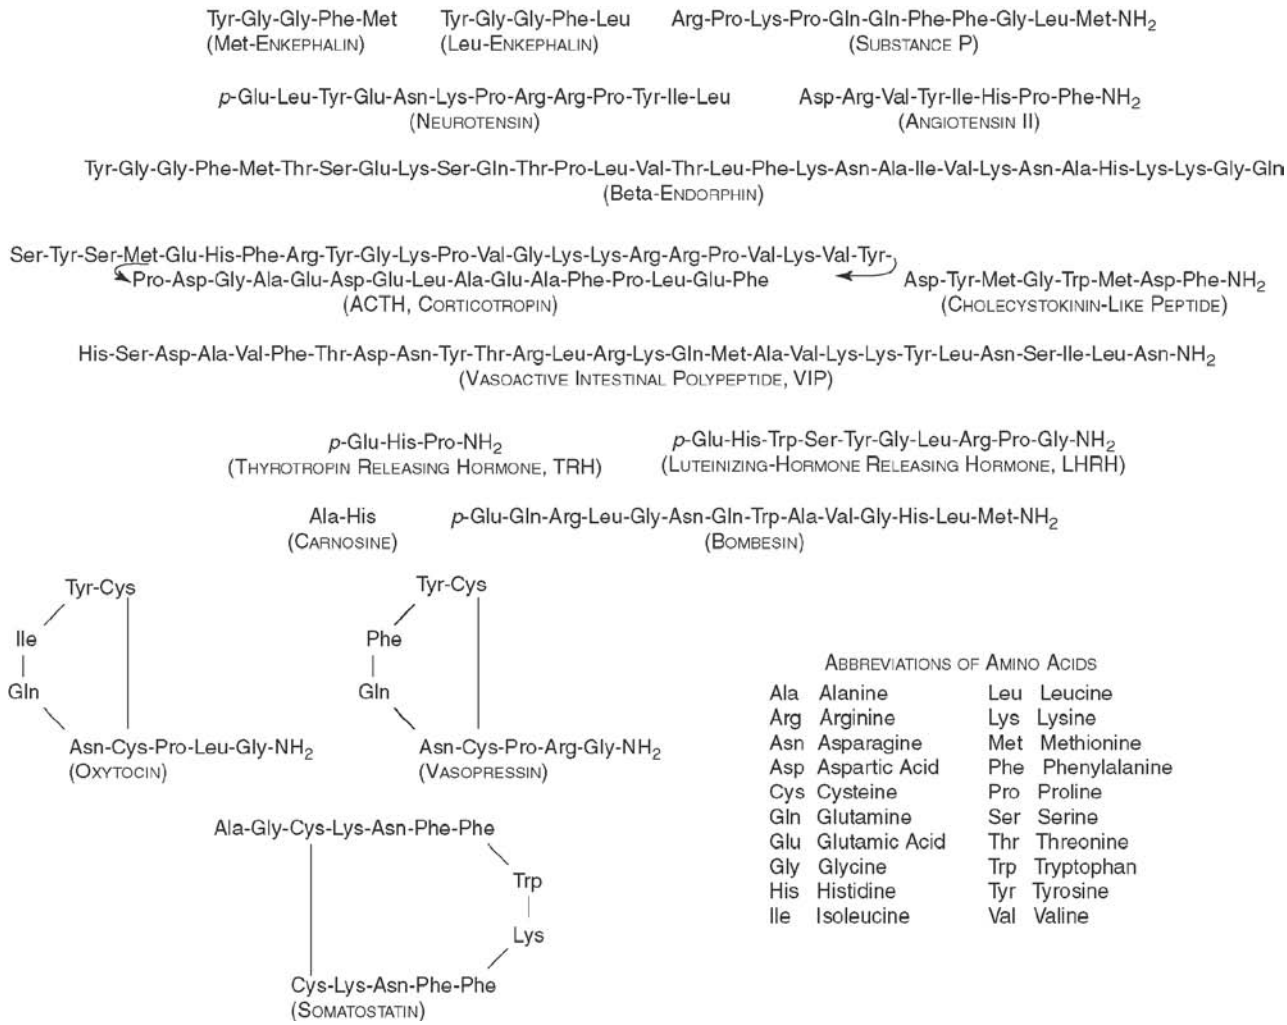

Fig. 1. Now believed to be transmitters, neuropeptides, which are short chains of amino acids found in brain tissue and notably localized in axon terminals, participate in complex mental activity, such as thirst, memory, and sexual behavior

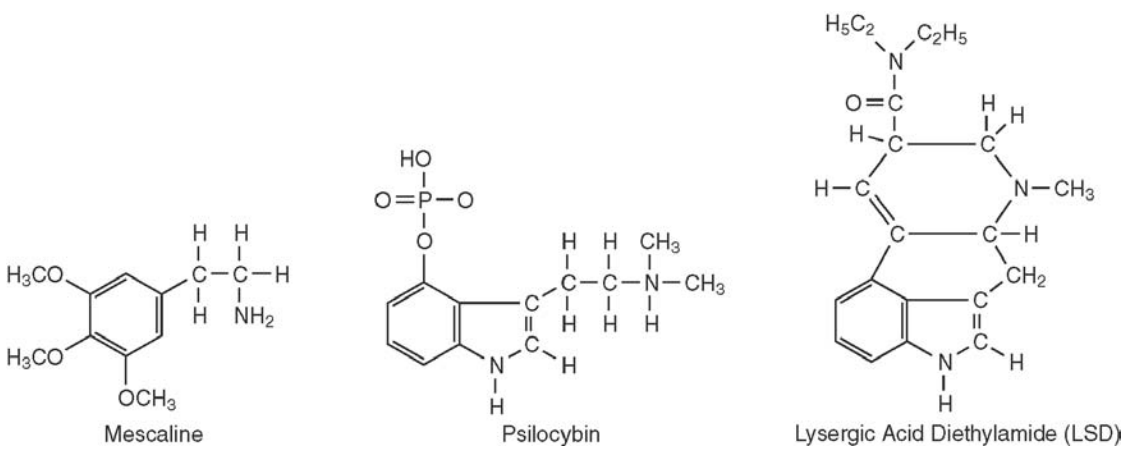

Fig. 2. Representative hallucinogenic drugs which bear structural similarities to some of the monoamine transmitters. It has been hypothesized that these similarities may cause the hallucinogens to mimic natural transmitters at synaptic receptors in the brain. Note presence of benzene-ring structure in these substances, a structure that is present in four out of the five monoamines previously shown. Also note presence of indole ring in psilocybin and lysergic acid diethylamide, a structure that is also present in the monoamines serotonin and histamine

located in those regions of the brain and spinal cord which are known to be associated with emotion and pain. Pioneering research in the field included the work of Snyder and Pert (Johns Hopkins University School of Medicine and Terenius (University of Uppsala). The enkephalins (Met- and Leu-), as shown in Fig. 1, were first isolated by Hughes and Kosterlitz (University of Aberdeen) in 1975. Each enkephalin contains five amino acids, one of these being methionine in one case, and leucine in the other case. Shortly after the isolation of these compounds, the endorphins, also morphinelike compounds, were isolated from the pituitary gland. Some researchers have suggested that some of the non-traditional methods used for relieving

chronic pain, such as acupuncture, direct electrical stimulation of the brain, and possibly hypnosis, may be effective because these procedures may cause enkephalins or endorphins or both to be released to the brain and spinal cord. The drug naloxone (*Narcan*®) blocks the binding of morphine and experiments have shown that naloxone also blocks the effects of the aforementioned pain-relieving procedures; hence the tentative hypothesis.

Early research findings indicate that neuropeptides are released from axon terminals through the presence of calcium ions known to be the releasing mechanism in connection with established transmitters. Thus, some investigators believe that the neuropeptides also may be transmitters. This is particularly true of a compound simply identified as *substance P*. See Fig. 1. Some investigators have found that substance P is associated with spinal neurons involved in pain stimuli.

One of the surprising findings of recent brain and central nervous system research is that chemical substances previously considered to be exclusive to the province of the brain have been found in organs outside the nervous system (e.g., somatostatin, neurotensin, and enkephalins have been found in the gut), and conversely, that other substances active in other organs, but not previously associated with the central nervous system, have been found in the latter (e.g., gastrin, vasoactive intestinal polypeptide (VIP), and cholecystokinin, traditionally associated with the gastrointestinal tract, but now found in the central nervous system).

Also among recent discoveries in brain chemistry are the so-called *trophic substances*, which are believed to be secreted from nerve terminals. One of these is *nerve growth factor* (NGF). It has been established that this protein is required for the differentiation and survival of peripheral sensory and sympathetic neurons. Another benefit of recent research is a better understanding of how psychoactive drugs interact with the brain and central nervous system. See Fig. 2.

ENRICHING INGREDIENTS (FOODS). See **Bakery Processes, Yeast-Raised Products**.

ENRICHMENT. 1. Also "secondary enrichment." The term applied by students of ore deposits to the natural processes by which the lower levels of an ore deposit are enriched at the expense of the upper levels, or the original protore. Particularly applied to lodes in which the sulfide ores have been concentrated by the leaching of the upper levels of the vein and redeposition below the groundwater table. Important ore minerals belonging to this type are chalcocite and argentite.

2. Any process which changes the isotopic ratio; in reference to uranium, it is a process that increases the ratio of ^{235}U to ^{238}U in uranium by separation of isotopes.

ENSEMBLE. A collection of similar systems considered in statistical mechanics. Ensembles were introduced by Gibbs, and their importance lies in the fact that the average behavior of a system in an ensemble can often be used to predict the behavior of an actual physical system. Usually, all systems in an ensemble are supposed to have the same number of constituent particles. Such ensembles are called *petit ensembles*. Examples of petit ensembles used extensively are the *microcanonical* and *macrocanonical ensembles*. In a *microcanonical ensemble*, the variation in energy (or other independent variable) of all the systems lies within an infinitesimal range. Over this range, the assembly is in statistical equilibrium. In a *macrocanonical ensemble*, there is present a collection of identical microcanonical ensembles. In both of them, and any other *canonical ensemble*, the distribution in energy of the system is given by the Boltzmann factor. In a *cooperative ensemble*, the interactions between the systems composing the ensemble are not negligible. The state of a given system is largely determined by the states of the neighboring systems, while in an *ideal ensemble*, such as a perfect gas or ideal solution, these interactions can be neglected.

The *density of an ensemble* is written as the quantity ρ defined in such a way that $\rho\, d\Omega$ is the fraction of systems in an ensemble that have values of the momenta and position coordinates of all the particles in the system corresponding to a point in gamma-space within the extension in phase $d\Omega$. For grand ensembles one must suitably alter this definition, *grand ensembles* being defined by Gibbs as ensembles that do not have the same numbers of particles. The most often used grand ensemble is the *grand canonical ensemble*, which has a density ρ defined by

$$\rho = e^{-q+vn-\beta\in}$$

where q is a (normalizing) constant, $\beta = 1/kT$ (k, Boltzmann's constant; T, absolute temperature), ε, the energy of the system, $v = \beta g$ (g, the partial thermal potential), and n the number of particles of the system.

ENSIGN FLY *(Insecta, Hymenoptera).* Small parasitic insects whose abdomen is elevated on a slender stalk above the thorax. It has been likened to a flag and gives the common name to the group. The ensign flies make up the family *Evaniidae*. In all species whose habits are known, the larvae are parasitic in the eggs of cockroaches.

ENSTATITE. The mineral enstatite is an orthorhombic pyroxene, rarely in distinct crystals, usually found as fibrous or lamellar masses or perhaps compact. It has one easy cleavage parallel to the prism; brittle with uneven fracture; hardness 5–6; specific gravity 3.2–3.4; luster pearly to vitreous, sometimes somewhat metallic in bronzite, a variety of enstatite carrying up to 15% ferrous oxide, FeO. Color grayish to greenish or yellowish-white, green and brown. Chemically, enstatite is a silicate of magnesium, $MgSiO_3$. It occurs in igneous rocks which are high in magnesium content, like gabbros, diorites, and pyroxenites, and less commonly in metamorphic rocks. Meteorites of both the stony and metallic types have been shown to contain enstatite. It has been found at many places in Europe, (the former Czechoslovakia, Austria, Bavaria, Germany, Norway), and the Republic of South Africa. In the United States it occurs in Putnam and St. Lawrence Counties, New York; Lancaster County, Pennsylvania; Jackson County, North Carolina, and near Baltimore, Maryland. The name enstatite is derived from the Greek word meaning *opponent*, in reference to its refractory nature; it is almost infusible. See also **Pyroxene**.

ENTERIC CAVITY. The digestive cavity, *enteron*. This cavity forms by the splitting or invagination of the inner germ layer early in embryonic (see also **Embryo**) development and persists as a sac with one opening to the exterior in the coelenterates and flatworms. In this form it is also called the archenteron.

In animals with a tubular alimentary tract the enteric cavity becomes the primitive gut. Its endodermal lining becomes the glandular digestive tissue and gives rise to large glandular masses in some species, and in the terrestrial vertebrates also produces the respiratory system.

ENTERITIS. Any inflammation of the small intestine, usually accompanied by fever, pain in the abdomen, diarrhea and other constitutional symptoms. The condition is commonly called gastroenteritis. See also **Diarrhea**.

ENTHALPY. The *enthalpy*, H or *heat content*, of a substance is a thermodynamic property defined as the *internal energy*, E, plus the product of the pressure, P, times the *volume*, V, of the substance

$$H = E + PV \tag{1}$$

The enthalpy is an extensive state function; its value depends only on the state and the amount of the substance and not on its previous history. It has the units of energy and it is usually expressed in calories (or kilocalories).

For a process at *constant pressure* ($\Delta P = 0$), in which the only work performed is the mechanical pressure-volume work ($P\Delta V$), the *change in enthalpy*, ΔH, is equal to the heat adsorbed by the system, q (hence the name heat content):

$$\mathrm{D}H = \Delta E + P\Delta V = q \tag{2}$$

This relation is a direct consequence of the definition of enthalpy by Equation (1) and of the mathematical statement of the first law of thermodynamics, namely that the change in internal energy, ΔE, is equal

to the heat adsorbed minus the work done ($q - P\Delta V$). It is clear that this thermodynamic relation does not define absolute values of enthalpy or internal energy. Changes in enthalpy, however, are readily measured by calorimetric techniques, and the relative enthalpy values are sufficient for all thermochemical calculations.

Enthalpy-Temperature Relation and Heat Capacity. When heat is adsorbed by a substance, under conditions such that no chemical reaction or state transition occur and only pressure-volume work is done, the temperature, T, rises and the ratio of the heat adsorbed, over the differential temperature increase, is by definition the heat capacity. For a process at constant pressure (following Equation (2)), this ratio is equal to the partial derivative of the enthalpy, and it is called the *heat capacity at constant pressure*, C_p, (usually in calories/degree-mole):

$$\left(\frac{\partial H}{\partial T}\right)_p = C_p \tag{3}$$

The temperature dependence of H for a substance remaining in the same physical state can be expressed as a function of C_p by integration of Equation 3.

If a substance undergoes a transformation from one physical state to another, such as a polymorphic transition, the fusion or sublimation of a solid, or the vaporization of a liquid, the heat adsorbed by the substance during the transformation is defined as the *latent heat of transformation* (transition, fusion, sublimation or vaporization). It is equal to the enthalpy change of the process, which is the difference between the enthalpy of the substance in the two states at the temperature of the transformation. For the purpose of thermochemical calculations, it is usually reported as a molar quantity with the units of calories (or kilocalories) per mole (or gram formula weight). The symbol L or ΔH, with a subscript t, f (or m), s, and v is commonly used and the value is usually given at the equilibrium temperature of the transformation under atmospheric pressure, or at 25 °C. For a substance undergoing one phase transformation, with a latent heat Δh_t, at a temperature T_t, the enthalpy change between two temperatures, T_1 and T_2, such that $T_1 < T_t < T_2$, is given by

$$H_T - H_T = \int_{T_1}^{T_t} C'_p\, dT + \Delta h_t + \int_{T_t}^{T_2} C''_p\, dT \tag{4}$$

where C'_p and C''_p are the heat capacities of the substance in the two different physical states. For several successive transformations, additional terms are added. Fig. 1 illustrates the temperature dependence of enthalpy and heat capacity.

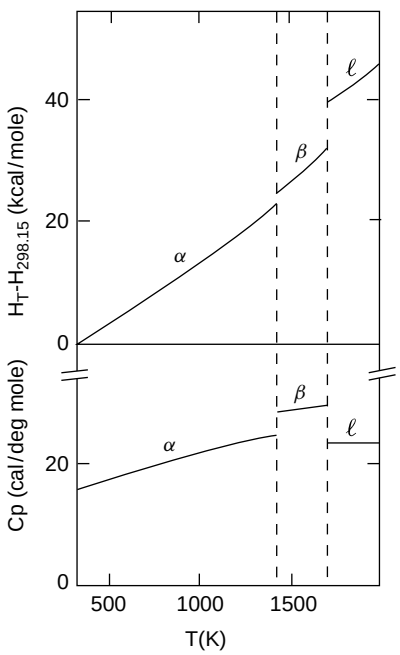

Fig. 1. Example of the temperature dependence of enthalpy relative to 25 °C, $H_T - H_{298.15}$, and heat capacity, C_p. The data are for fluorite, CaF_2 (*K.K. Kelly, 1960*). The discontinuities in the lines correspond to the α to β transition (1424 K) and the fusion (1691 K).

Very precise measurements of the heat capacity of liquids and solids can be obtained by calorimetric techniques at relatively low temperatures (below 200 °C) and they can be extrapolated down to the absolute zero of temperature (−273.15 °C) by reliable theoretical expressions. In that temperature range, heat capacity data are usually very accurate and enthalpy values are obtained by integration (Equation (4)). The most reliable method for determining high-temperature enthalpies and heat capacities is the dropping method (or method of mixtures) which consists of dropping the substance under investigation from a furnace at a known temperature into a calorimeter at room temperature. This method determines directly the change in enthalpy (or heat content) of the substance between the temperature of the furnace and that of the calorimeter. Heat capacities are obtained by differentiation (Equation (3)). The measurement of heat capacity of gases is usually more difficult, and their thermodynamic properties can be more accurately calculated by methods of statistical mechanics based upon energy level of gas molecules obtained from spectroscopic data, or upon the knowledge of the molecular configuration and the vibration frequencies of the molecules.

Molar enthalpy data for elements and inorganic compounds above room temperature are usually tabulated in the form of the heat content above a reference temperature, usually 298.15 °K = 25 °C. They are represented by: $H_T - H_{298.15}$ in calories/mole. The data are correlated over a range of temperature by empirical equations such as a series of powers of the absolute temperature or such as the following expression adopted by K.K. Kelley (1960) for his extensive compilation of data on inorganic compounds:

$$H_T - H_{298.15} = aT + bT^2 + c/T + d \tag{5}$$

where T is the absolute temperature (°K) and a, b, c, d are constants determined from experimental data. The corresponding equation for heat capacity is:

$$C_p = a + 2bT - c/T^2 \tag{6}$$

Standard Enthalpy of Formation. For the convenience of tabulation and computation of thermodynamic data, it is essential to present them in a commonly accepted form relative to a single standard state of reference. At all temperatures, the *standard state* for a *pure liquid or solid* is the *condensed phase under a pressure of 1 atmosphere*. The standard state for a *gas* is the *hypothetical ideal gas at unit fugacity* (equivalent to a "perfect gas" state), in which state the enthalpy is that of the real gas at the same temperature when the pressure approaches zero. Values of thermodynamic quantities for standard-state conditions are identified by a superscript ^{0}, and H^0, for instance, is the enthalpy change of a reaction when reactants and products are in the standard state.

The *standard enthalpy of formation*, ΔH_f^0 (also represented by ΔH_f^0 or simply H_f^0), of a substance at a given temperature is by definition, the enthalpy change when 1 mole of the substance in its standard state is formed, isothermally, at the indicated temperature from the elements, each in its standard state. Usual units are kilocalories/mole. *For all elements* in their *stable form at* 25 °C (298.15 K), the *enthalpy of formation is zero*. If solid substances have more than one crystalline form, the most stable one is taken as the standard state, and the others have slightly different enthalpies. This convention about zero enthalpy is arbitrary but universally accepted, and it may be compared to the arbitrary choice of zero for terrestrial altitudes. The combination of enthalpies of formation, enthalpies of transition, and heat capacities makes possible the calculation of the enthalpy of a substance, in a given state at a given temperature, relative to a commonly accepted reference.

Enthalpy calculation for mixtures is more complex than for pure substances and its discussion is beyond the scope of the present article. *Aqueous solutions* (q.v.), however, are very important from a geochemical point of view, and reliable data are usually available. The *enthalpy of solution* is the enthalpy change resulting from the dissolution of a substance; it is a function of the solute concentration and its values are reported accordingly in the literature. For a *solute in aqueous solution*, a *standard state* is defined as the *hypothetical ideal solution of unit molality* (1 mole of solute per 1000 grams of water). In this state, the partial molal enthalpy and heat capacity of the solute are the same as in the infinitely dilute real solution. Although it is impossible to prepare a solution of only one ionic species (since the system must remain neutral), it is convenient to apportion the enthalpy (and other thermodynamic properties) between the various ions. This appointment is not unique and an additional convention

has to be made, namely that the *standard enthalpy of hydrogen* ion in aqueous solution (aq) at unit activity, ΔH_f^0 for H^+ (aq), is *zero*. The properties of a neutral electrolyte in the standard state are equal to the algebraic sum of the values corresponding to the individual ions.

Heat of Reaction and Gibbs Free Energy Change. For a chemical reaction, at constant pressure with only pressure-volume work performed, the heat adsorbed by the process, q, is equal to the enthalpy change, ΔH, or the sum of enthalpies of the products of the reaction minus the sum of enthalpies of the reactants (taking into account the amount of each).

$$q = \Delta H = \Sigma H_{\text{products}} - \Sigma H_{\text{reactants}} \tag{7}$$

Those heat effects can be easily calculated when the enthalpies of formation and the enthalpy-temperature relations are available for the substances considered. Usually, the *heat of reaction* is defined as the heat evolved by the process, and it is equal to the enthalpy change but opposite in sign, while heats of fusion or vaporization always refer to the heat adsorbed, and for heats of solution the usage varies. In order to avoid any confusion, it is recommended to express heat effects of chemical process by reporting the enthalpy change, ΔH.

Early chemists thought that the heat of reaction, $-\Delta H$, should be a measure of the "*chemical affinity*" of a reaction. With the introduction of the concept of *netropy* (q.v.) and the application of the second law of thermodynamics to chemical equilibria, it is easily shown that the true measure of chemical affinity and the driving force for a reaction occurring at constant temperature and pressure is $-\Delta G$, where ΔG represents the change in thermodynamic state function, G, called *Gibbs free energy* or *free enthalpy*, and defined as the enthalpy, H, minus the entropy, S, times the temperature, T ($G = H - TS$). For a chemical reaction at constant pressure and temperature:

$$DG = \Delta H - T\Delta S \tag{8}$$

and the Gibbs free energy change can be obtained by calculating the enthalpy and entropy change and applying Equation (8). The criterion for *a spontaneous chemical reaction* is that ΔG be *negative*, and a chemical equilibrium corresponds to the condition $\Delta G = 0$.

Conversely, if the Gibbs free energy change is known as a function of temperature at constant pressure, the enthalpy change can be obtained by a relation which is an alternate form of the *Gibbs-Helmholtz equation*, and which can be derived from Equation (8).

$$\left(\frac{\partial(\Delta g/T)}{\partial(1/T)}\right)_P \Delta H \tag{9}$$

This means that ΔH is the slope of the line representing $\Delta G/T$ versus $1/T$ at constant pressure.

For references, see entries on **Heat Transfer**; and **Thermodynamics**.

ENTOMOLOGY. The science that deals with all facts pertaining to insects. Because of the large number of insect species and their frequent economic importance, the principal divisions of the science have been systematic entomology and economic entomology. Classification is difficult and intricate, and demands the constant service of specialists. The economic field is of such importance, especially to agriculture, that the national and state governments maintain organizations for the scientific study of insects that also assist in their control. See also **Insecticide and Pesticide Technology**.

Although entomologists may specialize in insect morphology or physiology, work of this type is less extensive than more practical studies and is of more general biological interest; hence, it takes its place largely in the subsidiary sciences of general biology.

ENTOPROCTA. The entoprocta are a small phylum of minute, solitary or colonial, sessile, aquatic animals. About 150 species have been described worldwide, with only one species occurring in freshwater. The colonial species encrust stones, shells and algae, and species have been described from all oceans. The solitary species are mostly associated with water-current-producing hosts, such as polychaetes, sponges and bryozoans; these species are not conspicuous and most of the reported distributions reflect specialists' searches.

Basic Design

Solitary species, and the zooids of colonial species, consist of a globular to flattened body attached to the substratum or a stolon with a dorsal stalk (Fig. 1.) The ventral side of the body is a concave atrium, surrounded almost completely by a horseshoe of ciliated tentacles. The stalk of the solitary species ends basally in a muscular sucker, a flexible, elongate foot with two types of glands, or is cemented permanently to the substratum. The stolons are cylindrical with incomplete septa between sections with zooids and sections without zooids. The body wall is a one-layered epithelium with microvilli penetrating a layer of crossing collagenous filaments. The stalks and stolons of the colonial species have a thickened cuticle with chitin. The body contains a U-shaped, ciliated gut with a flattened, funnel-shaped oesophagus, a large stomach, a conical intestine and a tubular rectum. The mouth is situated at the base of the tentacles on the anterior side of the atrium and the anus on the opposite side, near the break in the row of tentacles. A band of compound cilia follows the rim of the atrium with a loop onto each tentacle; a field of separate cilia surrounds the mouth and forms a food groove along the tentacle bases with extensions on the atrial side of each tentacle. At the anal side of the atrium, the band of compound cilia turns back and follows the food groove to the mouth. A dumbbell-shaped neural ganglion is situated at the upper side of the stomach near the oesophagus. Peripheral nerves extend to sensory cells and muscles in the tentacles, to sensory cells on the body and stalk, and to muscles in the stalk. Nervous connections between zooids have not been observed. Paired gonads and protonephridia are found just behind the ganglion. Most of the colonial species have a "star-cell complex" at the narrow transition between body and stalk. It consists of a stack of star-shaped cells with the tips of the rays attached to the ectoderm; the cells contain myofilaments and are pulsating, probably creating movement in the narrow fluid-filled primary body cavity. There is no trace of a coelom (secondary body cavity).

Diversity and Lifestyles

Four families are recognized. Loxosomatidae comprise solitary species, and Loxokalypodidae comprise a colonial species with zooids arising from a small basal plate. These two families lack the star-cell complex. Pedicellinidae and Barentsiidae are colonial with stolons and possess the star-cell complex. Pedicellinidae have stalks with continuous longitudinal musculature, whereas Barentsiidae have stalks with stiff segments and muscular joints.

Entoprocts are filter feeders, with the compound cilia of the tentacles forming downstream-collecting ciliary bands. The captured particles are transported along the frontal side of the tentacles to the food groove, which carries them to the mouth.

Most species are hermaphroditic, and the fertilized eggs are retained in the atrium until the larva is fully formed. Cleavage is spiral with mesoderm originating from the 4 d cell. The larvae are almost diagrammatic trochophores in a few species, but most species have larvae with a large ciliated, ventral foot. The released larvae have a shorter or longer planktonic phase and most of the larvae are planktotrophic. Some species of the solitary *Loxosomella* have a planktotrophic trochophore which settles with glandular cells around the frontal organ; their metamorphosis comprises a retraction of the foot, a constriction of the prototroch, and subsequently a reopening of the atrium surrounded by small, new tentacles. Other species of *Loxosomella* and species of *Loxosoma* have modified life cycles where one or two buds develop from the larval epithelium above the prototroch. When fully grown, the buds detach from the larval body, which disintegrates. The trochophores of pedicellinids and barentsiids retract the ventral side at settling and attach by secretions from glandular cells above the contracted prototroch. The internal organs rotate 180° with the mouth in front, and the atrium opens surrounded by a series of small tentacles.

Asexual reproduction through budding occurs in all species. Gut and atrial epithelium are formed from ectodermal invaginations, and ganglion and protonephridia develop from the ectoderm of the bottom of the atrium. In the solitary species the buds are formed from an area in front of the stomach and detach when all organs are fully formed. *Loxokalypus* has budding from a small basal plate. In the other colonial species the buds develop at the tips of stolons and remain attached as zooids in a growing colony.

Some of the colonial species make resting bodies (hibernacula), which are thick-walled mono- or multilocular cysts at the ends of short stolons.

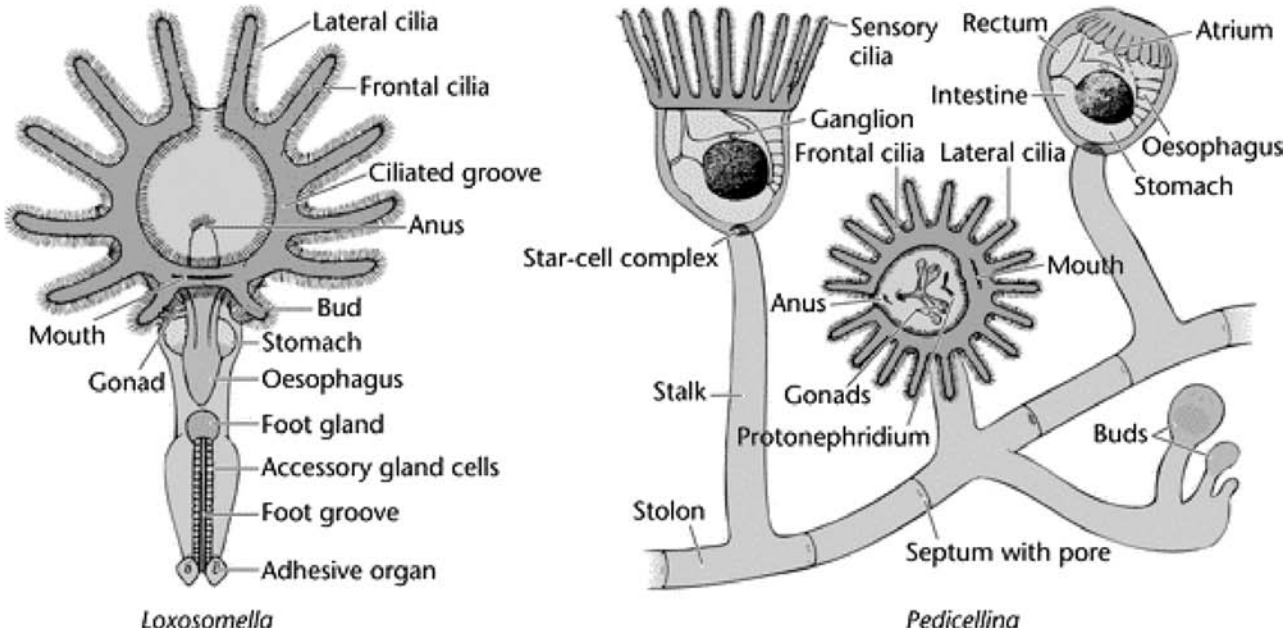

Fig. 1. A solitary (*Loxosomella*) and a colonial (*Pedicellina*) entoproct.

At germination, a new zooid is formed through a process similar to the normal budding.

Fossil History and Phylogeny

Specimen's strongly resembling recent species of the colonial genus *Barentsia* have been found in Jurassic deposits, where they have been preserved through bioimmuration, i.e. as moulds in calcareous matter secreted by cemented bivalves or tube-building polychaetes. See also **Fossil Record**.

The ancestral entoproct life cycle is probably represented by the species of the solitary *Loxosomella* which settle with the frontal organ and carry through an uncomplicated metamorphosis. The solitary species with larval budding and the colonial species appear derived.

The phylogenetic affinities of the Entoprocta are revealed by their spiral cleavage and trochophore larvae, which indicate that the phylum is closely related to other protostomes, such as annelids, mollusks, sipunculans, platyhelminths and nemertines. The relationships with the Bryozoa (Ectoprocta) is more uncertain. Molecular evidence is still inconclusive. See also **Annelida**; **Mollusks**; and **Platyhelminthes**.

CLAUS NIELSEN, Zoologisk Museum,Copenhagen, Denmark

ENTRAINMENT. 1. In meteorology, the mixing of environmental air into a preexisting organized air current so that the environmental air becomes part of the current; the opposite of detrainment. Entrainment of air into clouds, especially cumulus, is said to be inhomogeneous when the timescale for mixing of environmental air is very much greater than the timescale for drop evaporation. Under these conditions, which are often found when environmental air is first entrained into cumulus, regions of cloud and entrained air are intertwined, with evaporation occurring only on the edges of the interface between the cloudy and entrained environmental air.

2. The process by which turbulent fluid within a mixed layer incorporates adjacent fluid that is nonturbulent, or much less turbulent; thus entrainment always proceeds toward the nonturbulent layer. In the absence of advection effects, this tends to deepen the mixed layer.

AMS

ENTRAINMENT COEFFICIENT. The ratio of lateral entrainment velocity to plume-rise velocity of a smoke plume. Smoke plumes that rise through the environment due to buoyancy or momentum become diluted with environmental air, where the rate of dilution is proportional to the rise rate of the plume. The entrainment coefficient is this constant of proportionality. This concept of lateral entrainment does not work well for convective thermals in the atmospheric boundary layer. One reason is that boundary layer thermals are part of a large overturning circulation involving the whole boundary layer during statically unstable conditions of free convection, rather than being thin currents of rising smokestack air.

AMS

ENTRAINMENT VELOCITY. The volume of entrained air per unit area per unit time, which has units of velocity. It is a measure of dilution of an entity, such as a rising smoke plume, or of a whole layer, such as the atmospheric boundary layer. For a growing atmospheric mixed layer, the rate of rise of the top of the mixed layer z_i equals the entrainment velocity w_e minus any large-scale subsidence w_s that is imposed at the top of the boundary layer. During sunny days over land, the entrainment velocity is proportional to the heat flux from the surface divided by the potential temperature change across the entrainment zone (i.e., the strength of the capping inversion). On windy days, the entrainment velocity is proportional to the turbulence kinetic energy at the top of the boundary layer and is inversely proportional to the potential temperature change across the entrainment zone.

AMS

ENTRAINMENT ZONE. A layer of intermittent turbulence and overshooting thermals at the top of the convective mixed layer where the free atmosphere is entrained into the top of the boundary layer. Also called *entrainment layer*. The entrainment zone is thinner when a stronger temperature inversion caps the boundary layer and thicker when turbulence and thermals are more vigorous.

ENTRANCE SLIT. A narrow slit in an opaque screen through which light enters a spectrometer. The spectrum formed is the image of this slit in each wavelength of light present. A narrow slit is necessary for good resolution to avoid great overlapping of these images. However, the smaller the entrance slit, the less radiation enters the spectrometer. Hence a slit width must be used which is a compromise between the resolution desired and the necessary light intensity for proper observation or detection.

ENTRENCHED MEANDER. Also termed *incised meander*, a river valley which has a distinctly meandering old-age pattern (longitudinal profile), and a V-shaped or canyon-shaped, youthful transverse profile. The meandering course of the river is inherited from the time when it flowed at, or close to, base level, that is on a relatively flat surface. Subsequent uplift of the region quickens the flow of the stream, hence its downcutting power, without necessarily altering its inherited meandering course. Entrenched meanders are therefore physiographic evidence of the rejuvenation of the erosive power of an old-age stream. Entrenched meanders may suggest the first stage in a new cycle of erosion, but usually imply an interruption in the normal cycle due to relatively sudden uplift of the region before the entire area has been reduced to a peneplain.

ENTROPY. 1. In the mathematical treatment of thermodynamic processes there occurs very often a quantity, now relating energy to absolute temperature, now associated with the probability of a given distribution of momentum among molecules, and again expressing the degree in which the energy of a system has ceased to be available energy. Its mathematical form suggests that these are all aspects of a single physical magnitude. Application of the second law of thermodynamics leads to the conclusion that if any physical system is left to itself and allowed to distribute its energy in its own way, it always does so in a manner such that this quantity, called "entropy," increases. At the same time the available energy of the system diminishes. This law applies to the universe as a whole, hence the proposition that the total entropy increases as time goes on. An interesting conclusion as to entropy in the vicinity of absolute zero is expressed by the Nernst heat theorem; viz, that all physical and chemical changes in this region take place at constant entropy. Any process during which there is no change of entropy is said to be "isentropic." This is true, for example, of an adiabatic process in which there is no dissipation of energy, i.e., one which is also a reversible process. In thermodynamics discussions, entropy is commonly classed, along with temperature, pressure, and volume, as one of the variables defining the state of a body, and is often graphed as such on thermodynamic diagrams.

2. In information theory, entropy is a measure of the uncertainty of our knowledge.

3. In thermodynamics, entropy is defined by the equation

$$dS = dQ/T$$

where dS is an infinitesimal change in the entropy of a system, dQ is the infinitesimal amount of heat that enters the system, and T is the absolute temperature.

In statistical mechanics, entropy is

$$k \log_e P + \text{constant}$$

where k is Boltzmann's constant, and P is the statistical probability of the state considered.

Standard Entropy. The total entropy of a substance in a state defined as standard. Thus, the standard states of a solid or a liquid are regarded as those of the pure solid or the pure liquid, respectively, and at a stated temperature. The standard state of a gas is at 1 atmosphere pressure and specified temperature, and its standard entropy is the change of entropy accompanying its expansion to zero pressure, or its compression from zero pressure to 1 atmosphere. The standard entropy of an ion is defined in a solution of unit activity, by assuming that the standard entropy of the hydrogen ion is zero.

Entropy of Disorder. That part of the entropy of a substance that is due to a disordered arrangement of the particles as opposed to a similar but ordered arrangement. The most clear-cut example is the order-disorder transition in binary alloys, in which virtually the whole entropy change is of this kind. The entropy change on fusion of a solid is largely due to entropy of disorder.

See also **Energy**.

ENTRY CORRIDOR. Depth of the region between two trajectories which define the design limits of a space vehicle which will enter a planetary atmosphere.

ENUCLEATION. Enucleation is surgical removal of the eyeball, leaving, eye muscles eyelids, brow, and surrounding skin intact. This procedure is recommended only when all alternative treatments to preserve the eye have been exhausted or are inappropriate. Enucleation is typically performed to eliminate a life-threatening tumor within the eye, alleviate pain in a blind eye, or remove an eye severely traumatized by infection or injury.

Enucleation is a relatively simple operation that is normally performed under general anesthesia and takes about one to two hours. After the eye is removed, it is replaced with a plastic implant that is slightly smaller than the natural eye. This implant is designed to replace the volume in the socket that had been taken up by the eye. Muscles are reattached around the implant, and then the implant is covered with the conjunctiva, which is sewn into position to allow for healing. Sometimes a clear, plastic shell, known as a conformer, is placed behind the lids to give some shape while the socket heals.

Upon completion of the surgery, the eye is covered with a pressure pad and, although some patients may go home the same day, most stay in the hospital for one or two days. Pain relievers are prescribed as needed. Once the patch is removed, the eyelids may be swollen or bruised. Oral medications and eye drops and/or ointments are normally administered two to three times a day for several weeks.

Enucleation is a very safe procedure, and you will rarely experience significant complications, although the possibility exists. Complications can include, but are not limited to, bleeding, infection, swelling, and scarring.

After the eye socket heals, usually in three to six weeks, a specialist who makes artificial eyes will fit you for an ocular prosthesis. It is painted to resemble the other eye and inserted between the eyelids. The cosmetic appearance after enucleation is usually quite good, although your artificial eye may not move as well as your natural eye, and there may be some difference in the positions of the eyelids. Because you have sight only in one eye, depth perception is impaired. The human brain is very adaptable, however, and over time, you will relearn the skills of depth perception.

Enucleation is a traumatic procedure for most patients, and feelings of shock, depression, and concern about appearance are natural reactions to having an eye removed. Most patients adjust quickly, however, and continue to live a normal, happy, productive life. It is necessary to provide extra protection for the remaining normal eye.

Vision Rx, Inc., Elmsford, NY

ENVELOPE (Mathematics). The equation of a curve usually contains one or more constants, in addition to the dependent and independent variables. If the constants are regarded as variable parameters, a family of curves is generated as these parameters are assigned a series of different value. In case only one such parameter is involved, the equation for the family of curves can be written as $f(x, y, t) = 0$. If another curve, or group of curves, is a common tangent to the given family, it is said to be the envelope and it can be found by solving the two equations.

$$f(x, y, t) = 0; \partial f/\partial t = f_t(x, y, t) = 0$$

to obtain x and y as a function of the parameter t.

The procedure can be generalized for families of curves which depend on two or more parameters.

See also **Circular Curves**; **Robots and Robotics**; and **Tangent (Geometry)**.

ENVIRONMENT. The assemblage of material factors and conditions surrounding the living organism and its component parts.

Environment includes both external and internal factors. In the external environment inanimate objects and the forces associated with them constitute the physical environment, and the living things and their derivatives with which the animal may be associated constitute the organic environment. Within its body it maintains an organization which constitutes an internal environment to which all of its parts respond directly, whether or not they also have external contacts.

During the past few decades, the word *environment* has become a household word for numerous scenarios, but is used mainly to identify air, land, or water pollution. But this all-encompassing word also may refer to many more specific situations, such as: the deleterious effects of noise, nuclear and ionizing radiation; electromagnetic radiation that emits from cathode-ray tubes and power lines; to the contributions of

modern packaging to waste disposal and accompanying pollution; to the trade-offs between environmental and economic factors in selecting energy sources; or to the threat that light pollution may make obsolete some existing astronomical observatories — and the list goes on seemingly ad infinitum.

Thus, the staff of this *Encyclopedia* elected to place these various environmental concerns in their proper places, distributed throughout the two volumes, coupled with a convenient list of environmentally related topics in the alphabetical index.

ENVIRONMENTAL PROTECTION AGENCY (EPA). U.S. agency that ensures: Federal environmental laws are implemented and enforced effectively; U.S. policy, both foreign and domestic, fosters the integration of economic development and environmental protection so that economic growth can be sustained over the long term; public and private decisions affecting energy, transportation, agriculture, industry, international trade, and natural resources fully integrate considerations of environmental quality; national efforts to reduce environmental risk are based on the best available scientific information communicated clearly to the public; everyone in our society recognizes the value of preventing pollution before it is created; people have the information and incentives they need to make environmentally responsible choices in their daily lives; and schools and community institutions promote environmental stewardship as a national ethic.

Web Reference

Environmental Protection Agency: http://www.epa.gov/

ENVIRONMENT (Controlled). Frequently, in industry and research facilities, it is necessary to provide a planned and carefully controlled environment in which to conduct manufacturing, assembly, inspection, and test operations as well as scientific investigations. Clean rooms, temperature-controlled rooms, sound rooms, and dry rooms are terms that are often applied to special types of controlled environments. Some environmental systems are designed to control a single condition; in other cases, many variables are controlled. A clean room may require only dust particle control and a comfortable temperature for the personnel who work in the room. In the case of a room for calibrating dimensional standards and for measuring precision parts, very close temperature and humidity also will be required. Controlled environments, of course, also are required in hospitals and medical facilities, in horticultural establishments, in museums, and numerous other industrial and commercial structures. There is a fine division between what may be termed a controlled environment and what may be inferred from the term air conditioning. Essentially, a controlled environment differs from an air-conditioned space on two counts: (1) a controlled environment may include the measurement and very careful control of many environmental factors other than temperature and humidity which are the primary concerns of air conditioning, and (2) a controlled environment implies much greater precision in control and usually for reasons other than the comfort and well being of the occupants of a space. Further, a controlled environment may not even involve air, but rather may be concerned with the control of an aqueous environment, or of nonatmospheric factors, such as protection from shock, vibration, change of position, and so on.

Space does not permit a delineation of the many types of controlled environments encountered in industry and research. Because of the tight control requirements, an example is included of environmental control for a metrology standards laboratory and for so-called "clean rooms." The semiconductor industry also is a major user of clean rooms.

The International Organization for Standardization adopted 20 °C (68 °F) as the standard reference temperature for length measurement in 1951. Environmental systems for linear measurements provide temperature control at 20 °C ± 0.03 °C, maintain humidity between 40 and 45% (R.H.), and remove 99.97% of dust particles above 0.3 micrometer in size at the filter. Outside of the metrology laboratory, but in dimensional inspection rooms concerned with production parts, the temperature is controlled at 20 °C ± 0.60 °C.

Environmental rooms usually have air lock entry chambers. An air shower is included where critical control of duct contamination is required. A blast of air for a measured length of time is designed to remove foreign particles from an individual's outer clothing, usually a smock or uniform.

Generally, clean rooms using either vertical or horizontal laminar air flow are designed to control contamination and other variables as follows:

Particle Count — not to exceed 100 particles per cubic foot (approximately 3500 particles per cubic meter) of air of a size of 0.5 micrometer and larger.

Temperature — 72 °F ± 1 °F (22.2 °C ± 0.6 °C) under static conditions in a horizontal plane 1 foot (0.3 meter) above the floor.

Relative Humidity — 50% maximum. This depends upon use.

Air Velocity — 60 feet (18 meters)/minute (minimum) to 100 feet (30 meters)/minute (maximum), down to the floor in a straight-line flow.

Make-up Air — 15% minimum of total air used for air conditioning.

Positive Static Pressure — 0.05 to 0.10 inch (1.3 to 2.5 millimeters) of water.

ENZOOTIC. Term describing any disease of animals whose incidence and distribution resemble those of endemic disease in man.

ENZYME. An enzyme is a protein that serves as a catalyst for a particular biological transformation — as, for example, the conversion of sugar into alcohol and water. Because of the make-up of the genetic material, most enzymes are highly specific. As discussed in the article on **Industrial Biotechnology**, this specificity is very advantageous in bioprocessing.

Fermentation, one of the most common transformations to be accomplished with the aid of an enzyme as catalyst, has been known for about 4000 years, mainly in connection with brewing, winemaking, and dairy products, such as cheese and yogurt. It was not until the early 1600s that the concept of an enzyme was recognized. Well over 300 years passed by, however, before the first enzyme to be isolated, *urease*, was produced in crystalline form. Shortly thereafter, numerous other enzymes were isolated in pure form, including amylase, carboxy-peptidase, chymopapain, papain, pepsin, and starch phosphorylase. Today, there are many hundreds of known enzymes with many specific purposes. Enzymes, once created from microorganisms right in the fermenting vessel, can in some instances be purchased in pure form for addition to the fermentation batch vessel. As mentioned in the article on **Enzyme Preparations**, purified enzymes are widely used in the food industry for enhancing flavor and stabilization of food quality and, among other uses, are compounded in packaged detergents. Major classes of enzymes include the oxidoreductases, transferases, hydrolases, lyases, isomerases, and ligases or synthetases, their names indicative of their functions.

Sources of Enzymes. Enzyme complexes are generated by living cells, notably yeasts, molds, bacteria, and actinomycetes. Enzymes are involved in numerous biological transformations, as in the metabolism of living organisms, and thus play a vital role at practically all levels of food involvement — production, processing, and consumption, whether by fish, bird, insect, or primate. Enzymes and the transformations which they promote are ever present during the entirety of the food chain. Investigations in botany, pursuits of agronomy, studies of nutrition, inquiries into plant and animal pathology, and the numerous other aspects of science that are involved in life processes, when probed in depth, ultimately encounter the vital roles played by enzymes.

Characteristics of Enzymes

Although with the advent of gene recombination technology the knowledge of enzymes is gaining rapidly, their principal characteristics have been established for decades. These include sensitivity to the environment (temperature and pH), the need for a clean watery medium (solvent), the requirements for nutrients, such as carbon (for energy), oxygen (absence or presence depending upon whether microorganism involved is anaerobic or aerobic), nitrogen, phosphorus, and trace substances.

Common properties of enzymes include:

1. Their predominant, established role as catalysts, often providing the means of effecting chemical (biological) conversions that otherwise would be difficult and at lower rates of energy expenditure.
2. Their structure which suggests that enzymes are simple or conjugated proteins.
3. Their relatively high sensitivity to environmental conditions.
4. Their origin from living cells.

The environmental tolerance of enzymes closely parallels other substances associated with live processes. They tolerate a relatively narrow temperature span and with denaturation (deactivation) occurring at temperatures generally above 50 °C (122 °F). Greatly reduced activity usually occurs well above the freezing point of water. Enzymes have a low tolerance to a pH below 4.0, and a minimal to no tolerance of certain organic solvents (alcohol, acetone, etc.), and destruction by numerous organic and inorganic substances.

Unlike most inorganic catalysts, enzymes are very specific for the transformations they catalyze. An acid catalyst, for example, will yield glucose, fructose, and galactose in the hydrolysis of raffinose (a trisaccharide). But, the enzyme diastase will yield melibose and fructose; emulsin will yield sucrose and galactose. The glucosidic linkages are hydrolyzed at about equal rates with an acid catalyst, whereas the enzyme catalysts act on just one kind of linkage even though the difference in linkages is small. Whereas acids may catalyze numerous compounds, including amides, acetals, and esters, a given enzyme will confine its actions to a very specific compound or closely related group. This characteristics adds very much to the efficiency of the enzymes when used in bioprocesses.

Another advantage of enzymes relates back to their microorganism precursors. Through the application of genetic recombination technology, enzyme-source microorganisms can be customized, that is, a wild bacterium or fungus can be manipulated to call for more desirable properties and the elimination of undesirable characteristics. Mutation is one way to bring this about. As pointed out by Hopwood (see reference), in point mutation, one can change one base pair (example: adenine-thymine to guanine-cytosine; or a base pair on a short stretch of DNA may be deleted from a sequence. Such (spontaneous) changes occur naturally, but they happen rarely (one in a million). This frequency of mutation can be multiplied hundreds of time by exposing microorganisms to mutagenic x-rays, gamma rays, or neutrons. With this technique, one can hope to find the desired mutant by examining only hundreds or a few thousands of samples instead of millions.

Suitability for Bioprocesses. In addition to the very large role that enzymes play in life processes and medicine and in industrial fermentation and related processes, enzymes are finding a growing role in industrial products, such as detergents, where enzymes tend to break down proteins to water-soluble proteoses or peptones. Enzymes for such use must remain active at relatively high pH values (8.5 to 9.5) and remain stable for a long product shelf life. See also **Detergents**.

The great number of reactions catalyzed by the enzymes in living organisms can be indicated by mentioning some of the major types. They include: all the oxidation processes by which the organism obtains its energy — mechanical and thermal; the hydrolysis processes by which food carbohydrates, proteins, and fats are broken down into simpler molecules capable of direct oxidation or of use by the organism in constructing its own structure; and all the detoxification reactions by which many harmful substances that may be absorbed by the organism, as well as its normal waste products, are converted into forms suitable for excretion.

Activators. Most enzymes can function only with the assistance of certain other substances. These are broadly designated as *activators*, and are commonly grouped into two classes. The first is that of the nonspecific activators, which take no part in the conversion and appear to act by their effect upon the enzyme itself. The most important of these are the metallic ions K^+, Na^+, Rb^+, Cs^+, Mg^{2+}, Ca^{2+}, Al^{3+}, Zn^{2+}, Cd^{2+}, Cr^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}. The second class of activators, mentioned earlier in this entry, are organic molecules, which enter into the conversion itself, often as carriers of a particular group. These substances are the group discussed in the entry on **Coenzymes**. In general, they are regenerated in their original form by other processes, so that they are not strictly substrates. On the other hand, the nicotinamideadenine nucleotides, which act as hydrogen carriers for various oxidoreductase reactions, may well be regarded as substrates.

A *substrate* may be defined as a substance modified by the action of an enzyme, or by the growing upon it of microorganisms. A *coenzyme* is a low-molecular-weight organic substance that can attach itself and thus supplement specific proteins to form active enzyme systems.

Inhibitors and Primers. Two other adjunct substances are the *inhibitors*, which retard or block enzyme action; and the *primers*, which enhance, or in some cases, are essential to it. An example is the priming of polyribonucleotide phosphotransferase by short ribonucleotide polymers.

Structure of Enzymes. The knowledge of the structure of enzymes is growing at a rapid rate, but much research remains before a high confidence level can be established pertaining to even the fundamentals of certain basic conversions.

Molecular Biology of Enzymes

One of the early examples of molecular biology which occurred after the 1950s when the DNA molecular configuration was established, but before restriction enzymes were discovered (early 1970s) was the work of researchers during the late 1950s and early 1960s on investigating the enzyme *ribonuclease*. The systematic name of this enzyme is polyribonucleoside-2-oligonucleotide-transferase. This enzyme transfers a phosphate group from one position to another within a polynucleotide, forming a cyclic compound, and the pancreatic form of this enzyme can also catalyze the transfer of the phosphate group to water, which is a step in the depolymerization of RNA.

The molecular weight of this enzyme was found (by analysis of its constituent amino acids) to be 13,700. It was found to consist of a single polypeptide chain, internally cross-linked by four cystine residues, as evidenced by the lack of any drop in molecular weight to accompany the oxidation of all four cystines to cysteic acid, and also by the occurrence of only one terminal $-NH_2$ group, and one terminal $-COOH$ group.

From this point, the primary structure was fully determined. The *primary structure* of an enzyme, or other protein, is the number, length, and composition of the polypeptide chains, the linear arrangement of their amino acids, and the number and position of the cross-links between chains. (The geometrical configuration of the molecule, which is usually a three-dimensional coiled and folded structure, and the side chains and their interactions were not determined.)

To determine the primary structure, after oxidation of the disulfide bridges between the cysteine molecules, the enzyme was cleaved into a series of linear polypeptides by the enzymatic action of trypsin. The fragments were separated by chromatography, and their individual amino acids were split off by acid hydrolysis. Then by repeating this process with another enzyme, a different series of polypeptide fragments were obtained, because the chains split at different points. By studying the overlaps of the two series, the fragments could be arranged in linear order. Combining the peptide structure so determined with the amino acids found gave the provisional primary structure of the enzyme shown in Fig. 1.

The final step in complete elucidation of the three-dimensional structure of ribonuclease was made by researchers at the Roswell Park Memorial Institute, Buffalo, New York. This group, headed by Dr. David Harker, employed x-ray diffraction techniques. Roughly 500,000 diffraction points were recorded and the data so obtained was fed to a computer.

The elucidation of the structure of ribonuclease follows that of lycozyme by a group at London's Royal Institute headed by Dr. David C. Phillips, and that of the other protein, myoglobin, for which Dr. Max F. Perutz and Dr. John C. Kendrew of Cambridge University received the Nobel Prize in chemistry in 1962.

Note in this structure of enzyme that specific points are marked as those at which other enzymes act. This feature of "active sites" is characteristic of enzyme behavior. In the case of the enzymes trypsin or chymotrypsin, the active sites for peptide or ester hydrolysis contain the functional groups of two histidine residues and of a serine residue. The ester enters the active region, forming temporary bonds with the enzyme at that point, the $-OR$ group of the ester becoming bonded to a hydrogen atom of the enzyme. Then the bond between the hydrogen atom and the enzyme breaks, releasing the alcohol of the ester. As a next step, H_2O adds from the solution to the complex, and by another bond rupture, the acid part of the ester is released, leaving the enzyme in its original condition. The overall reaction is a simple hydrolysis of the ester,

$$R'COOR + H_2O \longrightarrow ROH + R'COOH$$

but a large number of steps may be involved.

The determination of sites of active centers is effected not only by splitting of enzymes, but also by treating them with temporary or permanent inhibitors, and determining their points of attachment. Other

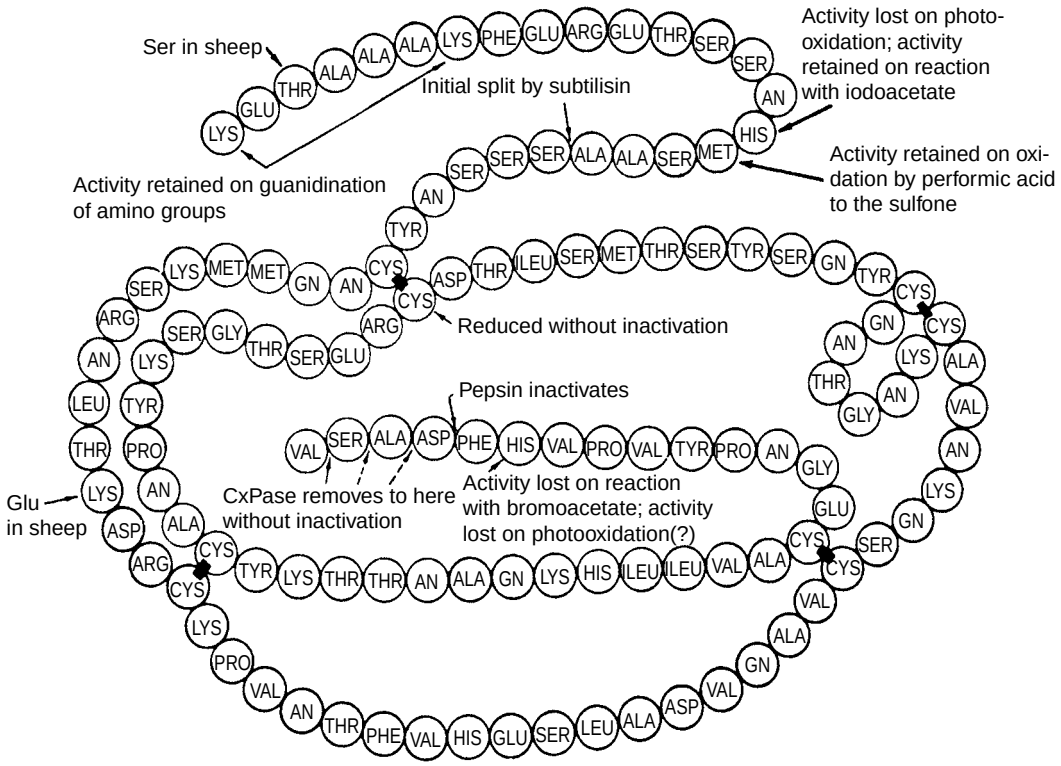

Fig. 1. Early representation of ribonuclease structure. Legend: Alanine (ALA), adenine (AN), arginine (ARG), aspartic acid (ASP), cysteine (CYS), cytosine (CN), glutamic acid (GLU), glycine (GLY), guanine (GN), histidine (HIS), isoleucine (ILEU), leucine (LEU), lysine (LYS), methionine (MET), phenylalanine (PHE), proline (PRO), serine (SER), threonine (THR), thymine (TN), tryptophan (TRY), tyrosine (TYR), uracil (UN), and valine (VAL).

methods of studying enzymes are by means of *enzyme induction* and *enzyme repression*.

Enzyme Induction. An example of *enzyme induction* is the growth of the bacteria *Escherichia coli* in a suitable culture medium. If no beta-galactoside is added to the medium, the bacteria form scarcely any of the enzyme that hydrolyzes that sugar. The addition of the sugar to the medium increases the production of the enzyme by the cell by as much as 10,000 times. On the other hand, the same bacteria will produce the enzyme tryptophan synthase only if tryptophan is absent from the culture medium. These observations are useful, not only in interpreting enzyme action, but also in determining its relationship to genetics, for in this case, the genes determining the ability to synthesize both enzymes are present on the chromosome map of the organism.

There are methods used to study enzymes other than those of chemical instrumental analysis, such as chromatography, that have already been mentioned. Many enzymes can be crystallized, and their structure investigated by x-ray or electron diffraction methods. Studies of the kinetics of enzyme-catalyzed reactions often yield useful data, much of this work being based on the Michaelis-Menten treatment. Basic to this approach is the concept that the action of enzymes depends upon the formation by the enzyme and substrate molecules of a complex, which has a definite, though transient, existence, and then decomposes into the products of the reaction. Note that this point of view was the basis of the discussion of the specificity of the active sites discussed above.

A simple enzyme reaction may thus be written as

$$E + S \rightleftharpoons ES \longrightarrow \text{products}$$

In the Michaelis-Menten treatment, this equation can be regarded as the result of the three processes:

rate of formation of $ES = k_1[E][S]$
rate of decomposition of ES into products $= k_2[ES]$
rate of decomposition of ES into original reactants $= k_3[ES]$

where the terms in square brackets denote concentrations of E, S, and ES, and the k's are rate constants. By representing the ratio $(k_2 + k_3)/k_1$ by K_m, the *Michaelis constant*, we can obtain a form of the Michaelis equation

$$\frac{[E_t]}{v} = \frac{K_m}{k_3 + [S]} + \frac{1}{k_3}$$

where E_t is the total concentration of enzyme (as distinguished from $[E]$, the concentration of free enzyme), and v is the velocity of the reaction. By plotting $[E_t]/v$ against $1/[S]$, we can obtain, at the axis-intercepts, values of $1/K_m$ and $1/v$.

This approach has been successfully extended to the more complex enzymatic conversions involving inhibitors, activators, and even multiple reactions in which the successive action of more than one enzyme is involved.

The observation follows that in addition to the specificity of the enzymes with respect to reaction type and to structure of the substrate, the action is also confined to a single configuration of the substrate. If the molecular structure of the substrate is unsymmetrical (asymmetric) and therefore two compounds exist — one the mirror image of the other — a specific enzyme will act upon only one of the stereoisomers. This specificity is undoubtedly due to the fact that the region of interaction on the enzyme is also asymmetric and exists in only one form or configuration. Racemic mixtures or certain substrates may sometimes be separated by making use of the fact that enzymic action will affect only one of the two forms.

Enzyme Repression. Repression as applied to biochemical reactions is a process of feedback control whereby a cell limits its production of the substances produced within it. An example that has been investigated shows the nature and mechanism by which this limitation is effected. It has been found that production of the amino acid L-isoleucine by cells of the bacterium *Escherichia coli* is repressed in the presence of an excess of the product. This excess is obtained experimentally by adding the substance to the culture medium in which the bacterium is grown. A form of the L-isoleucine is used that has been labeled with a radioactive isotope, so that the mechanism of the repression can be followed.

By this means, it has been found that the excess of L-isoleucine has two distinct effects — one that is relatively slow, and another that is rapid. The slower effect is to repress production by the cell of all the enzymes required to catalyze the series of biochemical reactions in the metabolic pathway by which the cell synthesizes L-isoleucine. The fast effect is to inhibit

TABLE 1. CLASSIFICATION OF ENZYMES

1. Oxidoreductases
   - 1.1 *Acting on the* CH−OH *group of donors*
     - 1.1.1 With NAD or NADP as acceptor
     - 1.1.2 With cytochrome as an acceptor
     - 1.1.3 With O_2 as acceptor
     - 1.1.99 With other acceptors
   - 1.2 *Acting on the aldehyde or keto group of donors*
     - 1.2.1 With NAD or NADP as acceptor
     - 1.2.2 With a cytochrome as an acceptor
     - 1.2.3 With O_2 as acceptor
     - 1.2.4 With lipoate as acceptor
     - 1.2.99 With other acceptors
   - 1.3 *Acting on the* CH−CH *group of donors*
     - 1.3.1 With NAD or NADP as acceptor
     - 1.3.2 With a cytochrome as an acceptor
     - 1.3.3 With O_2 as acceptor
     - 1.3.99 With other acceptors
   - 1.4 *Acting on the* CH−NH_2 *groups of donors*
     - 1.4.1 With NAD or NADP as acceptor
     - 1.4.3 With O_2 as acceptor
   - 1.5 *Acting on the* C−NH *group of donors*
     - 1.5.1 With NAD or NADP as acceptor
     - 1.5.3 With O_2 as acceptor
   - 1.6 *Acting on reduced* NAD *or* NADP *as donor*
     - 1.6.1 With NAD or NADP as acceptor
     - 1.6.2 With a cytochrome as an acceptor
     - 1.6.4 With a disulfide compound as acceptor
     - 1.6.5 With a quinone or related compound as acceptor
     - 1.6.6 With a nitrogenous group as acceptor
     - 1.6.99 With other acceptors
   - 1.7 *Acting on other nitrogens compounds as donors*
     - 1.7.3 With O_2 as acceptors
     - 1.7.99 With other acceptors
   - 1.8 *Acting on sulfur groups of donors*
     - 1.8.1 With NAD or NADP as acceptor
     - 1.8.3 With O_2 as acceptor
     - 1.8.4 With a disulfide compound as acceptor
     - 1.8.5 With a quinone or related compound as acceptor
     - 1.8.6 With a nitrogenous group as acceptor
   - 1.9 *Acting on heme groups of donors*
     - 1.9.3 With O_2 as acceptor
     - 1.9.6 With a nitrogenous group as acceptor
   - 1.10 *Acting on diphenols and related substances as donors*
     - 1.10.3 With O_2 as acceptor
   - 1.11 *Acting on* H_2O_2 *as acceptor*
   - 1.12 *Acting on hydrogen as donor*
   - 1.13 *Acting on single donors with incorporation of oxygen (oxygenases)*
   - 1.14 *Acting on paired donors with incorporation of oxygen into one donor (hydroxylases)*
     - 1.14.1 Using reduced NAD or NADP as one donor
     - 1.14.2 Using ascorbate as one donor
     - 1.14.3 Using reduced pteridine as one donor
2. Transferases
   - 2.1 *Transferring one-carbon groups*
     - 2.1.1 Methyltransferases
     - 2.1.2 Hydroxymethyl-, formyl-, and related transferases
     - 2.1.3 Carboxyl- and carbamoyltransferases
     - 2.1.4 Amidinotransferases
   - 2.2 *Transferring aldehydic or ketonic residues*
   - 2.3 *Acyltransferases*
     - 2.3.1 Acyltransferases
     - 2.3.2 Aminoacyltransferases
   - 2.4 *Glycosyltransferases*
     - 2.4.1 Hexosyltransferases
     - 2.4.2 Pentosyltransferases
   - 2.5 *Transferring alkyl or related groups*
   - 2.6 *Transferring nitrogenous groups*
     - 2.6.1 Aminotransferases
     - 2.6.3 Oximinotransferases
   - 2.7 *Transferring phosphorus-containing groups*
     - 2.7.1 Phosphotransferases with an alcohol group as acceptor
     - 2.7.2 Phosphotransferases with a carboxyl group as acceptor
     - 2.7.3 Phosphotransferases with a nitrogenous group as acceptor
     - 2.7.4 Phosphotransferases with a phospho-group as acceptor
     - 2.7.5 Phosphotransferases, apparently intramolecular
     - 2.7.6 Pyrophosphotransferases
     - 2.7.7 Nucleotidyltransferases
     - 2.7.8 Transferases for other substituted phospho-groups
   - 2.8 *Transferring sulfur-containing groups*
     - 2.8.1 Sulfurtransferases
     - 2.8.2 Sulfotransferases
     - 2.8.3 CoA-transferases
3. Hydrolases
   - 3.1 *Acting on ester bonds*
     - 3.1.1 Carboxylic ester hydrolases
     - 3.1.2 Thiolester hydrolases
     - 3.1.3 Phosphoric monoester hydrolases
     - 3.1.4 Phosphoric diester hydrolases
     - 3.1.5 Triphosphoric monoester hydrolases
     - 3.1.6 Sulfuric ester hydrolases
   - 3.2 *Acting on glycosyl compounds*
     - 3.2.1 Glycoside hydrolases
     - 3.2.2 Hydrolyzing N-glycosyl compounds
     - 3.2.3 Hydrolyzing S-glycosyl compounds
   - 3.3 *Acting on ether bonds*
     - 3.3.1 Thioether hydrolases
   - 3.4 *Acting on peptide bonds (peptide hydrolases)*
     - 3.4.1 α-Aminoacyl-peptide hydrolases
     - 3.4.2 Peptidyl-amino acid hydrolases
     - 3.4.3 Dipeptide hydrolases
     - 3.4.4 Peptidyl-peptide hydrolases
   - 3.5 *Acting on* C−N *bonds other than peptide bonds*
     - 3.5.1 In linear amides
     - 3.5.2 In cyclic amides
     - 3.5.3 In linear amidines
     - 3.5.4 In cyclic amidines
     - 3.5.5 In cyanides
     - 3.5.99 In other compounds
   - 3.6 *Acting on acid-anhydride bonds*
     - 3.6.1 In phosphoryl-containing anhydrides
   - 3.7 *Acting on* C−C *bonds*
     - 3.7.1 In ketonic substances
   - 3.8 *Acting on halide bonds*
     - 3.8.1 In C-halide compounds
     - 3.8.2 In P-halide compounds
   - 3.9 *Acting on* P−N *bonds*
4. Lyases
   - 4.1 *Carbon-carbon lyases*
     - 4.1.1 Carboxyl-lyases
     - 4.1.2 Aldehyde-lyases
     - 4.1.3 Ketoacid-lyases
   - 4.2 *Carbon-oxygen lyases*
     - 4.2.1 Hydro-lyases
     - 4.2.99 Other carbon-oxygen lyases
   - 4.3 *Carbon-nitrogen lyases*
     - 4.3.1 Ammonia-lyases
     - 4.3.2 Amidine-lyases
   - 4.4 *Carbon-sulfur lyases*
   - 4.5 *Carbon-halide lyases*
   - 4.99 *Other lyases*
5. Isomerases
   - 5.1 *Racemases and epimerases*
     - 5.1.1 Acting on amino acids and derivatives
     - 5.1.2 Acting on hydroxyacids and derivatives
     - 5.1.3 Acting on carbohydrates and derivatives
     - 5.1.99 Acting on other compounds
   - 5.2 *Cis-trans isomerases*
   - 5.3 *Intramolecular oxidoreductases*
     - 5.3.1 Interconverting aldoses and ketoses
     - 5.3.2 Interconverting keto- and enol-groups
     - 5.3.3 Transposing C−C bonds
   - 5.4 *Intramolecular transferases*
     - 5.4.1 Transferring acyl groups
     - 5.4.2 Transferring phosphoryl groups
     - 5.4.99 Transferring other groups
   - 5.5 *Intramolecular lyases*
   - 5.99 *Other isomerases*
6. Ligases or Synthetases
   - 6.1 *Forming* C−O *bonds*
     - 6.1.1 Aminoacid-RNA ligases
   - 6.2 *Forming* C−S *bonds*
     - 6.2.1 Acid-thiol ligases
   - 6.3 *Forming* C−N *bonds*
     - 6.3.1 Acid-ammonia ligases (amide synthetases)
     - 6.3.2 Acid-amino acid ligases (peptide synthetases)
     - 6.3.3 Cyclo-ligases
     - 6.3.4 Other C−N ligases
     - 6.3.5 C−N ligases with glutamine as N-donor
   - 6.4 *Forming* C−C *bonds*

production of the enzyme for the first reaction in the series. This enzyme is L-threonine deaminase, which removes the amino group from L-threonine, as a preliminary step to its oxidation and reintroduction of the amino group, in order to produce L-isoleucine from it.

The independent existence of these two effects was demonstrated by the discovery among mutations of *E. coli*, a mutation that exhibited only one of the effects, and of another mutation that exhibited only the other, leading to the conclusion that two distinct genes are involved in the control system.

An even more striking instance of feedback control is found in the synthesis of DNA (see also **Nucleic Acids and Nucleoproteins**). As pointed out in that entry, normal DNA is composed of the nucleotides deoxyguanosine, deoxycytidine, deoxyadenosine, and thymidine, and the amounts of the first and second of these are the same, as are those of the third and fourth. Obviously, close control is required of the amounts of these nucleotides that are synthesized by the cell, if they are to be made in the quantities required for DNA synthesis. Evidence has been found that the enzyme carbamoylphosphate: L-aspartate carbamoyl transferase, which catalyzes the conversion between aspartic acid and carbamoyl phosphate (which has deoxycytidine triphosphate, CTP, as its final product), is inhibited by an excess of the CTP, and is also initiated (or activated) by an excess of deoxyadenosine triphosphate, which requires an equal amount of CTP to react with it in forming DNA. There are thus both positive and negative feedback controls on the synthesis of the enzymes that catalyze the synthesis of the nucleotides. Since all enzymes are proteins, the mechanism of this control is believed to be that suggested for protein synthesis in the entry on **Nucleic Acids and Nucleoproteins**. See also **Genetics and Gene Science (Classical)**; and **Molecular Biology**.

An aspect of the control of enzymatic action that is related to the effect of initiation (or activation) just discussed is the effect of *induction*, which can readily be illustrated experimentally. Many years ago, it was found that the yeast, *Saccharomyces ludwigii*, although able to ferment many sugars, was ineffective on lactose (milk sugar), because it did not synthesize the necessary enzyme, lactase (ζD-galactoside galactohydrolase). However, if this yeast was grown for several generations on a medium containing lactose, it acquired the ability to make lactase, and its subsequent generations retained that ability. In the years since this discovery, so many instances of induction have been discovered that they are regularly cited in discussions of the properties of those enzymes for which they are known, as are also the repressing and blocking substances.

Classification of Enzymes by Function

As shown in Table 1, enzymes are classified into six groups: (1) oxidoreductases, (2) transferases, (3) hydrolases, (4) lyases, (5) isomerases, and (6) ligases or synthetases. The main group to which an enzyme belongs is indicated by the first figure of the code number. The second figure indicates the subclass. For the oxidoreductases, it shows the type of group in the *donors* which undergoes oxidation. For the transferases, it indicates the nature of the group which is transferred. For the hydrolases, it shows the type of bond hydrolyzed; for the lyases, the type of link that is broken between the group removed and the remainder; for the isomerases, the type of isomerization involved; and for ligases, the type of bond formed.

The third figure of the code number, indicating the sub-sub class, shows for the oxidoreductases the type of acceptor involved; for the transferases and hydrolases, it shows more precisely the type of group transferred or bond hydrolyzed; for the lyases, it shows the nature of the group removed; for the isomerases, it indicates in more detail the nature of the isomerization; and for the ligases, it shows the nature of the substance formed. Thus, an enzyme number, commonly indicated by the prefix EC, provides fairly detailed information about a specific enzyme.

Categories of Conversions. The comparative simplicity of the classification scheme bears testimony to the underlying unity of enzymatic catalysis.

Oxidoreductases. The overall conversion catalyzed by the oxidoreductases can be written as hydrogen transfer, and these enzymes might be considered to be merely one section of the transferases. The oxidoreductases are classified separately because of their large number and because of their great biological importance in bringing about the main energy-yielding conversions of living tissues.

Transferases. The main groups of transferases are concerned with the transfer of *one-carbon* groups, acyl groups, glycosyl residues, amino- and other nitrogen-containing groups, phosphate, and sulfate. Oxidoreductases and transferases together represent about half or more of the enzymes presently recognized. A general conversion for both oxidoreductases and transferases can be written:

$$AX + B \rightleftharpoons A + BX$$

Hydrolases. These enzymes include esterases, glycosidases, peptidases, deaminases, and enzymes which hydrolyze acid anhydrides (such as the pyrophosphate group in adenosinetriphosphate). Many hydrolases have been shown to be able, under appropriate conditions, to catalyze transfer conversions; a high concentration of acceptor is usually necessary, since there is competition between the added acceptor and water for the group transferred. The detailed mechanism in these cases probably involves transfer of a part of the substrate onto a group on the enzyme, with subsequent transfer to an acceptor or hydrolysis, e.g., for a hydrolase acting on a substrate AB to produce AOH and BH:

$$EH + AB \longrightarrow E - A + BH$$

and

$$E - A + X \longrightarrow E + AX$$

or

$$E - A + H_2O \longrightarrow EH + AOH$$

These hydrolases, if not all, can therefore be regarded as transferases which include H_2O among their possible acceptors. Under normal conditions, in aqueous solution, hydrolysis will be the dominant conversion.

Lyases. Enzymes in this grouping catalyze conversions of the type:

$$AX - BY \rightleftharpoons A = B + X - Y$$

Molecules, such as H_2O, H_2S, NH_3, or aldehydes, are added across the double bond of a second unsaturated molecule. Decarboxylases, such as those acting on amino acids can be regarded as lyases (carboxylyases), assuming CO_2 and not H_2CO_3 to be the immediate product of decarboxylation. Over one hundred lyases are known.

Isomerases. These include enzymes that bring about conversions similar to those in several other groups, but distinguished in that the reaction takes place entirely within one molecule, which is not cleaved, so that the overall reaction is

$$A \rightleftharpoons B$$

Thus, there are intramolecular oxidoreductases (e.g., ketolisomerases), intramolecular transferases (e.g., phosphomutases), and intramolecular lyases. About fifty isomerases are known.

Ligases. These enzymes catalyze conversions, which are more complex than those of the other groups, and must involve at least two separate stages in the reaction. The overall result is the synthesis of a molecule from two components with a coupled breakdown of adenosine triphosphate, or some other nucleoside triphosphate. In general, this may be written:

$$X + Y + ATP \longrightarrow XY + AMP$$
$$+ \text{Pyrophosphate(or ADP + Phosphate)}$$

These enzymes, of which many are known, are of great importance in the conservation of chemical energy within the cell and in the coupling of synthetic processes with energy-yielding breakdown conversions.

ENZYME PREPARATIONS. During the past several years, a number of commercially prepared enzyme preparations have been available to processors, notably for use in the food industry. These preparations fall into three basic categories: (1) Animal-derived preparations; (2) plant-derived preparations; and (3) microbially derived preparations.

Fruit juices, jams, and jellies, corn (maize) syrups and sweeteners, structured protein foods, and tenderized meats are exemplary of products, the quality of which has been improved through the use of enzyme preparations. Principal areas of development in food-grade enzyme research have been toward upgrading quality and byproduct utilization, higher rates and levels of extractions, synthetic food development, sweetener development, improving flavor of foods, and the stabilization of food quality and nutrition. Enzyme preparations also are used in the detergent field.

Animal-derived enzyme preparations include catalase (bovine liver), lipase, pepsin, rennet, and trypsin. Plant-derived preparations include bromelain, cellulase, ficin, malt, papain, and pectinase. Microbially derived preparations include amylases, carbohydrase, catalase, glucose oxidase, lipase, protease, and zymase.

EOCENE. A subdivision of the Tertiary Period of the geologictime-scale. Type locality, near Paris, France. Term first proposed by Lyell in 1832. The Eocene began approximately 60 million years ago and lasted for about 20–30 million years. The greatest thickness of formations of this period occur in Wyoming. The principal areas of deposition in the United States are: (1) the unconsolidated marine gravels, glauconite sands and clays which overlap the Cretaceous marine sediments of the Atlantic Border; (2) the marine limestones, terrestrial sandstones and lignites of the Gulf Coast; (3) the marine sediments of the Pacific Coast; (4) the terrestrial intermontane deposits of the Western interior. The plants of this period suggest worldwide warm climate. The fossil plants include many of the modern genera, such as the beeches, dogwoods, walnuts, maples and elms. Fossil vertebrate skeletons show that the mammals were by then dominant, although many of the existing orders of reptiles and birds also lived at this time. The mammalian fauna may be divided into two principal groups: (1) the archaic types which did not survive the Eocene; (2) the progenitors of the modern mammals, including the ancestors of the camels, pigs, horses, rats, and primitive monkeys. The principal surviving archaic forms are the creodonts (primitive flesh-eaters), uintatheria (hippopotamus-like forms), and zeuglodons (marine mammals). The mineral resources of this period are described under **Tertiary**.

EOLIAN DEPOSITS. Sediments and sedimentary rocks which are largely, if not entirely, composed of wind-blown material. Desert sands are typical aeolian sediments, characterized by relatively uniform, well-rounded particles whose surfaces are usually covered with microscopic pits due to their mutual bombardment during transportation. This pitting gives each sand grain a frosted appearance. Wind-blown sediments frequently show characteristic cross-bedding, ripple marks (miniature dunes) and wind-faceted pebbles (glyptoliths). Further evidence of their origin is the absence of fossils. Aeolian deposits are usually largely composed of quartz sand. An important fine-grained wind-blown deposit is loess. Extensive desert deposits are also composed of gypsum, salt, etc.

EOPHYTIC. A paleobotanic division of geologic time. This term signifies the time during which algae were abundant. See also **Paleobotany**.

EOSINOPHILIC FOLLICULITIS. See **Folliculitis**.

EOSINOPHILS. A type of white blood cell or leukocyte that stains a red color with eosin stain; normally about 2 to 3 percent of white cells in the blood but tending to decrease during stressful situations and thus usable as an index for stress.

EPHEMERIS TIME (ET). The uniform measure of time defined by the laws of dynamics and determined in principle from the orbital motions of the planets, specifically the orbital motion of the earth as represented by Newcomb's Tables of the Sun.

A gravitational ephemeris expresses the position of a celestial body as a function of ephemeris time; and, at any instant, the measure of ephemeris time is the value of the argument at which the ephemeris position is the same as the actual position at the instant. The ephemeris time at any instant is obtained from observation by directly comparing observed position of the sun, moon, and planets with gravitational ephemerides of their coordinates; observations of the moon are the most effective and expeditious for this purpose. An accurate determination, however, requires observations over a more or less extended period; in practice, it takes the form of determining the time correction T that must be applied to universal time (UT) to obtain ephemeris time:

$$ET = UT + T$$

The universal time at any instant may be obtained with little delay from observations of the dirunal motions.

The fundamental epoch from which ephemeris time is reckoned is the epoch that Newcomb designated as 1900 January 0, Greenwich mean noon, but which actually is 1900 January 0 day 12 hours ET; the instant to which this designation is assigned is the instant near the beginning of the calendar year A.D. 1900 when the geometric mean longitude of the Sun referred to the mean equinox of data was 279 degrees 41 minutes 48.04 seconds. Ephemeris time is the measure of time in which Newcomb's Tables of the Sun agree with observation.

The primary unit of ephemeris time is the tropical year, defined by the mean motion of the sun in longitude at the epoch 1900 January 0 day 12 hours ET; its length in ephemeris days is determined by the coefficient of T in Newcomb's expression for the geometric mean longitude of the sun L referred to the mean equinox of date, given among the elements of the sun.

Ephemeris (ephemerides). A periodical publication tabulating the predicted positions of celestial bodies at regular intervals, such as daily, and containing other data of interest to astronomers. *A publication giving similar information useful to a navigator is called an almanac.*

Ephemeris day. 86,400 ephemeris seconds.

Ephemeris second. This was the fundamental unit of time of the International System of Units of 1960: 1/31556925.9747 of the tropical year defined by the mean motion of the sun in longitude at the epoch 1900 January 0 day 12 hours. See *second* for the definition of the latest unit of time in the SI system or look on the WWW version of the National Institute of Standards and Technology: Physics Laboratory's International System of Units (SI).

Epoch. A particular instant for which certain data are valid, as the data for which an astronomical catalogue is computed.

Second. The unit of time, the second, was defined originally as the fraction 1/86 400 of the mean solar day. The exact definition of the "mean solar day" was left to astronomers, but their measurements have shown that on account of irregularities in the rotation of the Earth, the mean solar day does not guarantee the desired accuracy. In order to define the unit of time more precisely, the 11th CGPM (1960) adopted a definition given by the International Astronomical Union which was based on the tropical year [see *ephemeris second*]. Experimental work had, however, already shown that an atomic standard of time-interval, based on a transition between two energy levels of an atom or a molecule, could be realized and reproduced much more accurately. Considering that a very precise definition of the unit

of time of the International System, the second, is indispensable for the needs of advanced metrology, the 13th CGPM (1967) decided to replaced the definition of the second by the following:

The second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium-133 atom (13th CGPM (1967), Resolution 1).

Editor's Note: The previous is an excerpt (with the exception of the reference to "ephemeris second") from the WWW version of the National Institute of Standards and Technology: Physics Laboratory's International System of Units (SI).

See also **Time**.

EPHEMEROPTERA. The mayflies, also known locally as shad flies, salmonflies, and June bugs. The adults are sluggish insects with slender filaments at the caudal end of the body and large triangular front wings. The hind legs are much smaller, in some species rudimentary. The immature insect is aquatic and in most species feeds on decaying vegetable matter. It may live for several years, while the adult stage lasts only a few days. See Fig. 1.

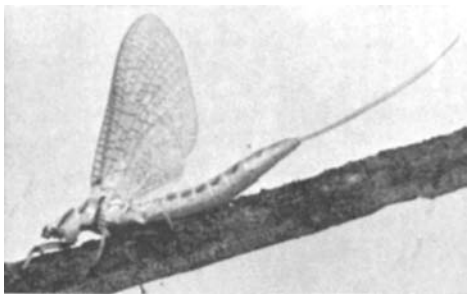

Fig. 1. Mayfly (*Ephemeroptera*). (*A.M. Winchester*.)

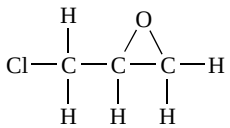
Mayflies of one species emerge as adults in large numbers within a short period and are sometimes very abundant near favorable bodies of water. They fly at twilight and can sometimes be seen in large gray clouds at a distance of more than a mile over the islands of Lake Erie, where they are especially abundant. In the cities bordering the lake they are attracted to lights and their dead bodies are sometimes swept up in bushels after a heavy flight. Under such conditions they are a nuisance but not a serious pest. Their value as food for fishes more than offsets what little harm they do.

EPICARDIUM. 1. The thin covering of the vertebrate heart, continuous with the lining of the pericardial cavity.

2. Outgrowth from the branchial sac in many ascidians, which takes part in budding.

EPICHLOROHYDRIN. A highly reactive and industrial important compound with the structural formula



It is also called 1-chloro-2,3-epoxypropane and is classified as an organic epoxide. The compound is a colorless, clear, mobile liquid with an odor something like chloroform. Molecular weight, 92.53; freezing point, $-57.1\,^{\circ}$C; boiling point, $116.07\,^{\circ}$C; density 1.1750 g/cm^3 at $25\,^{\circ}$C with reference to water at $4\,^{\circ}$C. Solubility is 6.53 g/100 g of water. Epichlorohydrin is made by the chlorohydrination of allyl chloride, in which 1,2-dichlorohydrin and 1,3-dichlorohydrin are produced as intermediates.

One of the most common epoxy resins is produced by the reaction between epichlorohydrin and bisphenol A. See also **Epoxy Resins**. The compound also is used in the production of epichlorohydrin-based rubbers which have good aging, high resiliency, and flexibility at low temperatures, advantage of which is taken in automotive and aircraft parts, seals, gaskets, hose, belting, wire, and cable jackets. These rubbers also have good resistance to solvents, fuels, oils, and ozone. A number of wet-strength resins for use in the paper industry also are derived from epichlorohydrin, including (a) epichlorohydrin-modified polyamides; and (b) the addition of epichlorohydrin to high-molecular-weight polyalkylene polyamines. The advantages of these resins is that no alum or acid medium is required for incorporating the resin into the cellulose pulp. During the drying process, the resin cross-links and thus yields a paper with permanent wet-strength properties. Ion-exchange resins also can be prepared by reacting epichlorohydrin with ethylene diamine or a similar amine. The resulting material is a stable, water-insoluble anion-exchange resin.

In addition to its use in the production of epoxy resins epichlorohydrin is used in large quantities in the manufacture of glycerin. Other uses include textile applications where it is used to modify the carboxy groups of wool, thus increasing durability and improving moth resistance; in the synthesis of antistatic agents, wrinkle-resistant agents, and coating sizings. Effective against the larvae of certain insects, the compound is used in control chemicals for agriculture where permitted.

EPICONTINENTAL SEAS (or Epicontinental Marginal Seas). Shallow bodies of water deeper than continental shelves and having somewhat greater relief, generally somewhat greater than 600 feet (180 meters) in depth. See also **Continental Shelves**.

EPICYCLIC GEAR TRAIN. Combinations of gears having a motion resulting from rotation about an axis which, in itself, is in rotation, are known as epicyclic trains. A simple epicyclic gear train, consisting of three gears and an arm, is shown in Fig. 1. Mechanism of this nature is sometimes used for speed reducers. The ratios of speed of the driven and driving elements are found by the following simple rule: consider, first, the gears locked and the entire mechanism turned one revolution; then the arm locked and the fixed gear turned one revolution in the opposite direction to the first step. The algebraic sum of these two separate motions will give the absolute number of turns of any gear, and from this the speed ratio may be found.

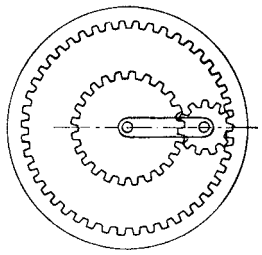


Fig. 1. Epicyclic gear train.

EPICYCLOID. A higher plane curve, which is a special case of a cyclic curve. A circle of radius r rolls around the outside of a fixed circle of radius R and a point on the circumference of the moving circle traces out the curve. Its equation in parametric form is

$$x = (R + r)\cos\phi - r\cos\frac{(R + r)\phi}{r}$$

$$y = (R + r)\sin\phi - r\sin\frac{(R + r)\phi}{r}$$

The curve consists of a set of congruent arches. See Fig. 1. The first one will occur at some value of ϕ between 0 and $2\pi r/R$ and the kth one between $2\pi r(k-1)/R$ and $2\pi kr/R$. It will not repeat itself, however, unless $2\pi kr/R$ is a multiple of 2π for k, an integer. This means that $r/R = m/n$, where m/n is a rational fraction. Thus $k = n$, there are n arches to the curve, an equal number of cusps, and it winds around the fixed circle m times.

The special case of $r = R$ is called a cardioid. If the generating point for the epicycloid is at a distance $a \neq r$ the curve is an epitrochoid.

If an epicycloid rolls on a straight line, the locus of the center of the fixed circle is an ellipse, which is called the roulette of the epicycloid. The evolute of an epicycloid is a similar epicycloid.

See also **Cardioid**.

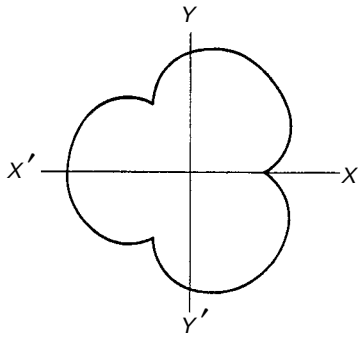

Fig. 1. Epicycloid.

EPIDEMIOLOGY. That branch of medical concerned with the study of disease as it appears in its natural surroundings, and as it affects a community of people rather than a single individual. Epidemiology is largely concerned with infectious diseases; it has a statistical as well as an experimental side. The statistical includes the gathering of facts about the incidence, mortality rate, relation of climate, age, sex, race and many other factors to the appearance of a given disease. From these data, valuable information that is important in controlling epidemics of disease is obtained. In experimental epidemiology, the investigator may produce epidemics in laboratory animals for the study of certain problems, or he may go out in the field and study epidemics in man by laboratory means. Such work is important in elucidating the cause, the modes of transmission, and the insect vectors possibly concerned, as well as other facts of fundamental importance in public health. Numerous governments throughout the world maintain statistical and data processing centers which provide periodic reports on many aspects of diseases. Most states and provinces maintain their own records and also report and exchange information with a central government office, such as the Centers for Disease Control of the U.S. Public Health Service, located in Atlanta, Georgia.

Epidemiology in connection with foodborne diseases is discussed in some detail in the entry on **Foodborne Diseases**.

EPIDERMIS. In insects, the outer layer of the noncellular cuticula; here the cellular layer is called the hypodermis. In other invertebrates the cellular layer covering the body is called the epidermis. In vertebrates, the epidermis is the outer cellular layer of skin. The human epidermis consists of four layers, from without to within follows: (1) a layer of horny flattened cells, (2) a layer of transparent cells, (3) layers of granular cells, (4) a layer of rounded pigmented cells. The outermost layer of cells on the younger parts of plants is also called the epidermis. See also **Dermatitis and Dermatosis**.

EPIDERMIS (PLANT). The epidermis is the protective outer layer of clonally related cells covering all plant organs. It is composed of a number of specialized cell types which differentiate from the basal epidermal cell in adaptively significant frequencies and patterns.

Plants are composed of a number of tissue types which are organized interactively to produce organs. The dermal tissue system, or epidermis, is the outer tissue system. In most plant organs it comprises a single layer of cells. The single cell depth of the epidermis is maintained by the purely anticlinal divisions within the layer, which drive the expansion of the sheet of cells in only two dimensions. All cells within the epidermis are thus clonally related while the tissue as a whole is clonally distinct from other cell layers. However, plasmodesmatal connections allow the exchange of certain molecular information between cell layers, so the epidermis is not biochemically isolated from other tissue systems. The main function of this outer sheet of cells is a protective one, with a waxy cuticle on the outer cell walls reducing the risk of dehydration, predation or invasion of the photosynthetic tissues below. However, within this protective skin a number of different specialized cell types with roles in gas exchange, protection and attraction differentiate and the development of the epidermis is thus an exercise in patterning to promote effective multifunctionality (Fig. 1a).

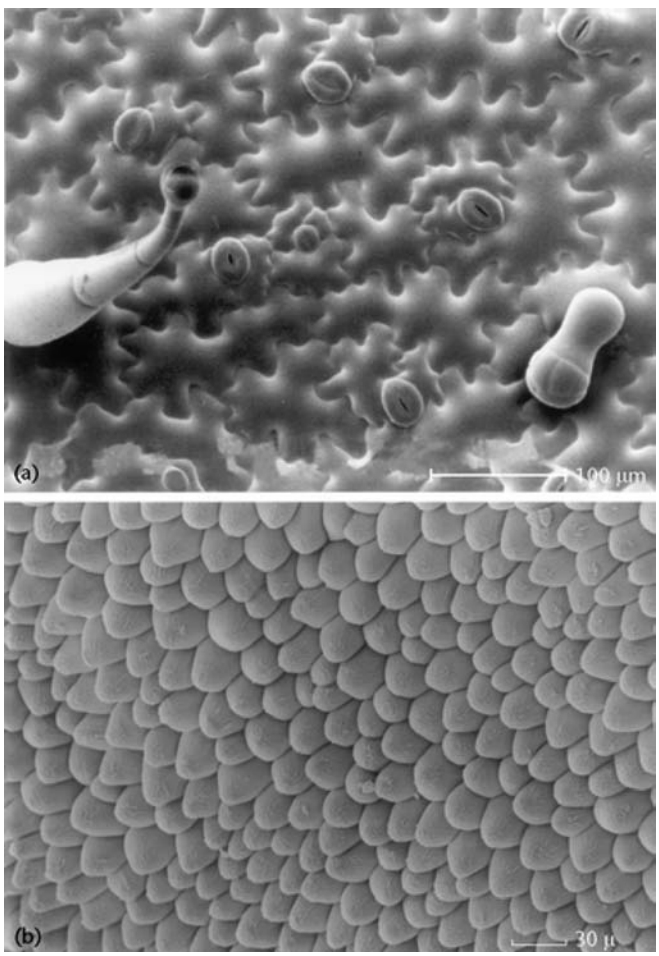

Fig. 1. (**a**) Adaxial epidermis of tobacco leaf showing spacing of stomata guard cells, two different types of trichome and pavement cells. (**b**) Adaxial epidermis of rose petal. All cells adopt the conical-papillate form with heavy cuticular striations.

Origin in Embryo

The epidermis originates in three discrete events in the developing plant embryo. The shoot epidermis, defined as the epidermal tissue overlying all organs above the cotyledons, develops from the L1 layer of the shoot apical meristem. The shoot apical meristem develops early in embryogenesis in the dip between the cotyledons at the heart stage. The outer layer of cells in this region will produce all the epidermal cells of the plant leaves, stem, aerial branches and floral organs, and these cells will all be clonally related as divisions in the shoot L1 are purely anticlinal. The root apical meristem develops from the basal pole of the embryo. It is first organized near the beginning of the heart stage and has a dual origin, being derived from both cells of the pro embryo proper and the upper cell of the suspensor. The root epidermis is clonally related to the lateral root cap, as both tissues are produced by divisions of a ring of 16 initials in the root apical meristem. The epidermis between the shoot and root apical meristems, which covers the cotyledons and hypocotyl, is formed at a very

early stage of embryogenesis. By the globular stage, 16 cells, the outermost cells, or protoderm, are already dividing exclusively anticlinally. This is necessary in order to produce a skin large enough to cover the dividing cells underneath. The protoderm is also uncoupled from information exchange with other cell layers, isolating it further. Thus, the epidermis arises from the L1 layer of the shoot apical meristem and the lateral root cap initials of the root apical meristem as a sheet of clonally related cells but is assembled on the outer surface of the rest of the embryo by isolation of a single cell layer.

Cell Types in L1

Meristematic L1 cells are indistinguishable from one another, being small rounded cells with very little vacuole. Indeed, with one or two exceptions, for as long as cell division continues in the epidermis, most L1 cells maintain this shape. However, once cell division has ceased in the epidermal layer of a developing organ and cell expansion has taken over as the dominant morphogenic process, each epidermal cell differentiates into one of a suite of possible specialized forms.

Stomatal Guard Cells. Stomatal guard cells are kidney-shaped epidermal cells in pairs surrounding the stomatal pore. They have thickened rigid inner walls which cause them to expand outwards, opening the pore, when their turgor pressure increases. Their function in regulating gaseous exchange is crucial to plant fitness and as such their patterning and development is highly regulated. See also **Stomate (or Stoma)**.

Trichomes. Trichomes are defined as projections from the aerial epidermis of the plant. This definition includes thorns, glands and papillae, but is used most commonly with regard to hairs, which may be unicellular or multicellular. Hairs defend plants against predators and the disease agents they carry by acting as simple barriers, or through a number of more complex mechanisms including hooking insects to the leaf and secreting toxic compounds through hair tip glands. Hairs may also be involved in regulating the boundary layer around a leaf and thus gas exchange and temperature. Thorns are involved in plant defense, while glands may secrete toxins for defense, digestive enzymes for carnivory or excess salts. Papillae are found on petals where they are involved in attracting pollinators and on the stigma where they trap pollen grains. See also **Trichomes**.

Pavement Cells. Pavement cells are the most numerous epidermal cells, found in all organs, and fulfill the dual functions of protecting the internal tissues and spacing out the more specialized cell types. Although commonly regarded as relatively unspecialized, they do exhibit features of morphology which reflect the function of the organ in which they are found. Leaf pavement cells, for example, have interlocking jigsaw puzzle shapes to increase tensile strength. The pavement cells of the root epidermis are known as atrichoblasts.

Root Hairs. Root hairs, or trichoblasts, are single cells in the root epidermis with very long tubular extensions produced by tip growth. The extension is derived from the lower part of the epidermal cell, and each root hair cell has only one such extension. These extensions dramatically increase root surface area and play a vital role in water and nutrient uptake. In *Arabidopsis*, root hairs differentiate on files of epidermal cells which overlay two files of cortical cells [Galway, et al., 1994]. Files of cells overlaying a single cortical cell file do not develop extensions. See also **Root (Plant)**.

Development of Epidermis, Patterning

The development of the epidermis proceeds first though anticlinal cell divisions to produce the sheet of cells and then differentiation of certain cells within that sheet to specialized fates.

Two pattern-generating mechanisms have been postulated to explain the distribution of specialized cells in the plant epidermis. The cell lineage mechanism of pattern formation relies on an ordered system of often asymmetric cell divisions to divide cells into different categories. Different categories of cells may then differentiate as alternate cell types. Thus the terminal differentiated state of a cell is a predictable result of its status in a lineage of cells occupying a certain position. It is through this mechanism that the basic patterning of *Arabidopsis* stomatal complexes is determined. The cell interaction mechanism of pattern formation relies on interactions between cells to reinforce any tiny initial differences to produce significantly different cells which may then adopt different fates. The cell interaction mechanism does not rely on cell position or lineage, and so cells contributing to the development of a single structure may be clonally unrelated. The patterning of *Arabidopsis* trichomes is controlled through a cell interaction mechanism, with developing trichomes inhibiting differentiation of neighboring cells. The cell interaction mechanism may, like the cell lineage mechanism, rely on progress through the cell cycle to distinguish between cells, but it is not dependent on actual cell division [Schnittger, et al., 1999].

Genetics of Development

The development of the epidermis of the mature plant is dependent on the proper function of the shoot and root apical meristems. Although several mutants are known which disturb meristem formation and maintenance, none are known which specifically disturb only one layer of the meristem. However, the *Arabidopsis* mutant *knolle* fails to develop the embryogenic epidermis covering the hypocotyl and cotyledons. Divisions in the outer cell layer of the *knolle* mutant are not uniformly anticlinal. *KNOLLE* has been cloned and encodes a protein with homology to syntaxins, proteins which act as plasma membrane targets for secretory vesicles [Lukowitz, et al., 1996]. This suggests that one possible role for KNOLLE is in the informational isolation of the outer layer, allowing it to develop epidermal characters. It is interesting to note that the *knolle* mutant embryo does have a few epidermal features associated with its outer layer. It is therefore possible that positional information alone is sufficient to determine some of the epidermal features of the outer layer, but isolation from the inner layers is necessary for complete transition to epidermis.

Trichome development in the *Arabidopsis* leaf epidermis is the best-studied example of epidermal patterning. The *Arabidopsis* trichome is a large unicell which develops through uncoupling of DNA synthesis and cytokinesis. At least three genes, *TTG* (*TRANSPARENT TESTA, GLABRA*), *GL1* (*GLABROUS 1*) and *TRY* (*TRIPTYCHON*), are involved in the patterning of *Arabidopsis* trichomes [Hülskamp, et al., 1994]. *TTG* encodes a WD40 repeat protein [Walker, et al., 1999], *GL1* encodes a MYB transcription factor [Oppenheimer, et al., 1991] and *TRY* has not yet been cloned. *TTG* and *GL1* are thought to be necessary for the uncoupling of DNA synthesis from cytokinesis. *TRY* is required for lateral inhibition of neighboring cells and therefore the correct spacing of trichomes. *GL1* is initially expressed in all epidermal cells but is later restricted to developing trichomes. It is not currently known how the decision as to which cells should continue to express *GL1* and thus differentiate into trichomes is made.

Fewer genes involved in stomatal patterning have been identified, perhaps because of the lethal nature of guard cell development mutants. However, two *Arabidopsis* mutants with lesions in stomatal patterning have been described. The *too many mouths* (*tmm*) mutant produces excess numbers of clustered stomata on some organs, but reduced numbers of stomata on other organs, notably the cauline leaves. The gene product is believed to be involved in determining meristemoid (precursor cell) number. The *fourlips* (*flp*) mutant also generates clustered guard cells, as a result of lesion in a gene believed to regulate cell division in the meristemoid [Yang and Sack, 1995].

Several genes involved in root hair patterning have been identified in *Arabidopsis*. Mutation at either the *TTG* or *GLABRA2* (*GL2*) loci results in ectopic production of root hairs on epidermal cell files, which do not usually produce hairs [Galway et al., (1994; Masucci et al., 1996]. Like *TTG*, *GL2* also plays a role in aerial trichome development, as mutants develop only short, stumpy trichomes. *GL2* encodes a homeodomain transcription factor. It appears that both TTG and GL2 function in root hair patterning by activating the nonhair fate in atrichoblasts. This contrasts markedly with their roles in trichome development, where TTG specifies the hair fate and GL2 controls later morphogenesis of the committed trichome cell.

The papillae or conical cells which increase the attractiveness of petals to pollinators by enhancing light absorption by pigment have also been studied at the molecular genetic level. In the snapdragon, *Antirrhinum majus*, mutation of the *MIXTA* gene results in flat petal epidermal cells. *MIXTA* encodes a MYB transcription factor [Noda, et al., 1994]. Differentiation of the multicellular trichomes common to many species may also require the activity of a *MIXTA*-like gene, since ectopic expression of *MIXTA* in tobacco results in the differentiation of excess numbers of these trichomes as well as the development of conical cells [Glover et al., 1998]. See also **Petals**.

Cell Shaping–Cuticle

The final appearance of a differentiated epidermal cell is defined by the patterning of the cuticle over that cell. The cuticle is a waxy layer of cutin-containing polymers secreted from epidermal cells after gross cell morphogenesis is complete. It acts as a barrier against water loss and increases the integrity of the plant against predators. However, in certain epidermal cells it is secreted in specialized patterns which contribute to the final cell form. One example of this is the *Arabidopsis* trichome, over which cuticle is secreted in a globular pattern. The potential function of this pattern is unknown. The conical-papillate cells of the petal epidermis also have highly patterned cuticle, and in this case a number of hypotheses have been proposed to explain the patterning. Most conical petal cells have a stellate pattern of cuticular striations, radiating outwards from the center of the cone (Figure 1b). These striations might provide functional support for the highly vacuolate cell, or they may have a role in pollinator attraction. Light reflection, refraction and absorption may all be influenced by these tiny striations. See also **Plant Waxes**.

EPIDIORITE. A term applied to gabbros, dolerites, and diabases, the augite of which has been partly altered to hornblende, thus approaching a diorite in mineral composition. The term is derived from the Greek, meaning upon, plus diorite.

EPIDOTE. This mineral is a hydrous silicate of calcium, aluminum, and iron with the formula, $Ca_2(Al, Fe)_3Si_3O_{12}(OH)$. The ratio of aluminum to iron ranges from 6:1 to 3:2. Epidote is found in prismatic monoclinic crystals, which may be acicular to fibrous. Fine granular and compact masses are common. The mineral displays one good cleavage, an uneven fracture; is brittle; hardness, 6–7; specific gravity, 3.25–3.5; luster, vitreous to resinous; typical color, pistachio green, but may be yellowish- to brownish-green, sometimes red, yellow, gray, white or colorless. Colorless to grayish streak; transparent to opaque. The characteristic color of ordinary epidote makes it usually an easily identified mineral.

It occurs commonly in metamorphic rocks as gneisses and schists; however, it seems probable that under certain conditions it may appear as a primary mineral, for example in granitic rocks. The Urals, Austria, Switzerland, Italy, France and Norway are known for their occurrences of fine epidote crystals. In the United States epidote has been found in excellent specimens at Franconia and Warren, New Hampshire; Huntington, Massachusetts; Willimantic and Haddam, Connecticut; Chaffee County, Colorado, and Riverside County, California. The word epidote is derived from the Greek. The name pistacite, from the Greek word meaning pistachio nut, has been occasionally applied to this mineral. It has been used as a gemstone but is in little demand for this purpose.

EPIGENETIC. A term used by petrologists to denote physical and chemical changes, particularly in igneous and sedimentary rocks, which are clearly secondary to (later in time) the conditions under which the rock originated. This term is commonly used by the students of ore deposits to designate minerals formed after the enclosing wall rocks, in contrast to those minerals formed contemporaneously with the wall rocks. The latter minerals are said to be syngenetic. In the case of the sedimentary rocks, the term is used to describe textures, structures and mineral aggregates, of nonmetamorphic origin, which have originated during the postlithification history of the formation. Thus flint, chert, and concretions, may be described as being either epigenetic or syngenetic.

EPIGLOTTITIS. The pharynx is a common passageway of the respiratory and digestive systems. See also **Pharynx**. A valve-like structure at the base of the tongue, the *epiglottis*, projects backward over the larynx during swallowing, and thereby prevents food from entering the larynx. *Acute epiglottitis*, an infection of this valve, is one of the most rapidly progressive and sometimes more lethal than any of the other infections of the upper respiratory tract — particularly among children between ages of 2 and 8 years. The condition starts suddenly, with very severe sore throat and fever, leading to dysphagia (difficulty in swallowing). There may be retention of secretions and drooling. Respiratory obstruction may occur within a few hours. The condition may occur in adults, but progresses more slowly because of the larger size of the airway in an adult.

Acute epiglottitis is considered a medical emergency. Inasmuch as examination of the pharynx may not produce an accurate diagnosis and because tongue depressors may elicit spasms, an immediate lateral-view x-ray of the neck should be made. Frequently, swelling of the epiglottis will be indicated. Where the x-ray does not satisfactorily confirm the condition, indirect laryngoscopy may be undertaken. Tracheostomy is the usual means taken to provide a restoration of the airway. Nasotracheal intubation is also used. To avoid delays, direct laryngoscopy may be undertaken. An important element of diagnosis is that of distinguishing epiglottitis from croup caused by viral laryngitis or other laryngeal conditions, and other possible causes of airway obstruction. In the case of croup, the epiglottis will be normal or only mildly inflamed.

The principal cause of acute epiglottitis is *H. influenzae* Type B. However, other pathogens may be involved. They include pneumococci, streptococci, and staphylococci. Physicians stress the need for immediate action in these cases, the initial therapy usually consisting of high-dose intravenous chloramphenicol (but considering its side effects) and penicillinase-resistant penicillin. Steroids may be administered to reduce edema and a mist tent may be a helpful supportive measure to assist breathing. In about half of the cases of this disease, nasotracheal intubation or tracheostomy is required.

EPILEPSY. Epilepsy is a central nervous system disorder that is characterized by unprovoked, recurrent seizures that disrupt communication among brain cells. It is considered one of the nation's most common disabling neurological disorders. Although epilepsy is often amenable to clinical treatment through medications, surgery, and diet, it can be a life-altering condition for persons affected by it. These life-altering effects result in part from the unpredictability of the seizures, which can curtail, to some degree, daily activities such as driving, school attendance, and employment. Persons with epilepsy and seizures also contend with the discrimination and misunderstanding of those around them. Thus the result of decades of stigma and misunderstanding about the disorder and its consequences.

Even with its unique manifestations, epilepsy shares characteristics with a variety of chronic conditions. It affects many aspects of a person's life,

it is relatively difficult to detect, and it tends to contribute to morbidity rather than mortality.

The seizures that characterize epilepsy reflect many different causes: some known, but most unknown. In children, important causes of seizures are birth and neonatal injuries, vascular insults, congenital or metabolic disorders, head injuries, infection, neoplasia, and heredity. In adults, the most common identifiable causes are vascular lesions, head trauma, drug or alcohol abuse, neoplasia, infection, and heredity. However, for both children and adults, a definite cause cannot be determined in many cases. The likelihood of experiencing the onset of seizures is highest in the first year of life, then decreases in adolescence. Following adolescence, the incidence of epilepsy remains relatively constant until about age 60, after which it rises dramatically. The risk of ever having a seizure is about 9%. About 3% of the population will be diagnosed with epilepsy after having more than one seizure. In the United States, more than two million people are being treated for epilepsy. Many more cases are likely, but undetected.

An accurate diagnosis of epilepsy is the first step in effectively managing the disorder. In 1989, the Commission on Classification and Terminology (under the auspices of the International League Against Epilepsy) developed a widely accepted classification system based on seizure type and epilepsy syndromes. Seizure type refers to whether the seizure is partial, generalized, or unclassified, with many finer distinctions in each category. Epileptic syndromes are categorized according to whether they are localization-related (focal, local, or partial), generalized, indeterminate, or special. EEGs, along with clinical histories, physical examinations, CT scans, and MRI, are used to determine the epilepsy syndrome.

Only half of patients with epilepsy are diagnosed within the first six months of the disorder's onset; it takes five years for 85% of patients to be diagnosed. Early, accurate diagnosis after the first seizure is critical because the second seizure can cause greater harm. In addition, a prolonged period without seizure control increases risks for social, psychological, and neurological difficulties that could otherwise be prevented or alleviated.

Initiating treatment with medication after a single seizure is controversial, since it is difficult to determine with certainty whether a first seizure is a unique occurrence or the first sign of chronic epilepsy. Such decisions may secondarily affect other areas of life, such as driving and employment.

Once the clinician has determined that a patient's seizures are not the result of an underlying treatable problem, antiepileptic drug therapy is initiated, preferably with a single agent and at the lowest possible dose.

For the majority of patients, drug treatment is effective; however, as with other chronic conditions, the physician and patient must find the specific therapy that offers the greatest seizure control and the fewest and most tolerable side effects. Key treatment issues include nonadherence with antiepileptic regimes (which occurs with 40 to 60% of adult patients and 25 to 75% of pediatric patients) and patient self-management, such as monitoring seizures and psychosocial reactions to the fear of seizures.

Approximately 20% of patients who receive antiepileptic drug therapy experience recurring seizures. Partial seizures are considered to be more likely to be intractable than other forms of epilepsy. Options in these situations include referral to specialized epilepsy centers for additional medication management, use of nonpharmacologic treatment devices, surgery, or some combination of the above.

EPIPELAGIC ZONE. The uppermost and very shallow layer of water in the oceans into which sufficient light passes to enable phytoplankton to convert the available carbon dioxide into food by means of photosynthesis. This zone, rarely more than 700 feet (210 meters) in depth, is the habitat of the major part of the sea's living matter.

EPIPHORA. Epiphora is an overflow of tears, usually caused by insufficient drainage of the tear film from the eye. The most common cause is a blockage of the lacrimal (tear) ducts located next to the nose, but the condition may also result from the excessive production of tears. Epiphora is a symptom rather than a disease and may be caused by a variety of conditions.

The purpose of normal tears is to lubricate, nourish, and protect the eye from dust and other irritants. Spread by blinking (about every six seconds), tears keep the surface of the eye optically clear and smooth, and also protect from infection. Tears flow into the eye through ducts from tiny glands located under the upper eyelids and drain from the eye through the puncta (singular: punctum), which are small openings near the nose.

A portion of tears evaporates, but the excess normally drains into the nose via the lacrimal canals and then into the throat or out through the nostrils. These types of tears are made continuously and are known as basal cell secretions. Reflex tears, on the other hand, are those produced in response to emotions or when the eye is very irritated. These are produced by a separate gland called the *lacrimal gland*. Basal tearing is more important for the health of the eye, but the volume of tears produced by the reflex mechanism is larger.

It is important to differentiate between chronic epiphora, acute epiphora, and normal tearing. Chronic epiphora results from a long-standing or continuous disorder. Acute epiphora usually results from a temporary condition such as a foreign body in the eye or environmental factors such as wind, pollen, eyestrain, emotional stress, and sleep deprivation. The chronic variety nearly always requires treatment by a professional. Acute epiphora may or may not require treatment, depending on the severity of the condition. Everyone experiences an occasional overflow of normal tears.

Occasionally children are born with congenital epiphora, which is usually related to incomplete development of the tear duct drainage system. This disorder often disappears without treatment during the first six months of life. If it remains, consult an ophthalmologist to determine the cause and treatment.

The most common cause of epiphora is blockage of the lacrimal ducts located along the nose. This blockage can be from a variety of causes including membrane inflammation, injury, or tumors. In adults, tear duct blockage can occur at any point in the lacrimal system from the punctum to the bottom of the nose.

Other causes of excess tearing may be corneal disorders, lower eyelid looseness, weakness of facial muscles as the result of a stroke, and eyelashes rubbing on the cornea. None of these causes are related to tear duct blockage.

One of the most common causes of excess tearing in older adults is dry eye syndrome. Ironically, one of the symptoms of dry eye can be excessive watering of the eyes. The watering is a natural reflex caused by irritation to the eye because the composition of the tears is incorrect. Normal tears are comprised of three layers: the *lipid*, or oil layer; the *lacrimal*, or watery layer; and the *mucoid*, or mucus layer. All three layers of tears are necessary for proper lubrication. Persons with dry eye syndrome have tears that are mostly water and evaporate quickly, providing little protection for the eye.

Symptoms of epiphora include excessive tearing, matting of the eyelashes, and mucous or pus like discharge from the puncta. Excess tearing can cause infection and, if left untreated, could be detrimental to good vision. Eyelid irritation is common because the area remains wet. Patients often complain because they must constantly wipe their eyes.

Because epiphora can be caused by a wide variety of disorders, a proper diagnosis by an eye doctor is necessary before treatment begins. If the excessive tearing results from a punctal obstruction, the most common treatment is for the doctor to open (dilate) the puncta and wash it out (irrigate). This is a simple in-office procedure, but is not a permanent solution and must be repeated several times a year.

An obstruction of the nasolacrimal duct (a tear duct that ends in the mucous membrane of the nose) is often treated by a procedure called a

dacryocystorhinostomy (DCR). During the DCR procedure, the obstruction in the duct is bypassed with a balloon-tipped probe creating a new passage as it is inflated. A temporary tube is then left in place to keep the new passage from scarring and closing. No incision is required, and the procedure can be performed under local anesthesia in an ophthalmologist's office.

When the epiphora is caused by dry eye, a variety of measures can be employed to alleviate the symptoms. Artificial tears in the form of eyedrops are the most common treatment. Many of these eyedrops are available over-the-counter and are used to lubricate the eye. A humidified environment also helps in dry eye treatment by adding moisture to the air and by helping prevent the evaporation of tears. Frequent blinking to spread tears is helpful, and avoiding smoke, wind, and other irritating conditions may provide relief.

If excessive tearing lasts for an extended period of time, see an ophthalmologist to determine the exact cause so that appropriate treatment can be initiated. See also **Dry Eye**; and **Tears**.

Vision Rx, Inc., Elmsford, NY

EPIPHYSIS. An area of cartilage near the ends of long bones which ossifies separately and later becomes part of the long bone; bone growth in length takes place in this area until ossification halts growth. Also called *epiphyseal cartilage*. See also **Bone**.

EPIPHYTES. A striking feature of tropical forests is the abundance of plants which grow attached to other plants. These attached plants are called epiphytes, which means plants growing on other plants. They are found both on the main trunk and on the branches, often far above the ground. In many cases the epiphyte grows on the under side of a branch to which it is firmly fastened by its roots. Epiphytes gain nothing but support, and a more favorable position of growth because of better light conditions and other environmental factors; they do not obtain any nutrients from the supporting plants, as parasites would. Particularly noteworthy among epiphytes are many ferns, aroids and especially orchids. Frequently, as in the orchids, the roots of the plants are so modified as to absorb water directly from the atmosphere.

In the strictest meaning of the word, many lower plants including algae, fungi, lichens and mosses are epiphytes, since they are often found growing on other plants, not only in tropical regions but in temperate regions as well.

EPISTASIS. The inhibition by a gene at one locus on a chromosome of the expression of a gene at another locus. This form of suppression should be distinguished from simple dominance, which is associated with members of allelic pairs. The gene that does the inhibiting is said to be epistatic to the gene that is inhibited. The gene that is suppressed is said to be hypostatic. For instance, the gene for albinism is epistatic to the gene for black coat color in guinea pigs. A guinea pig may be homozygous for the dominant gene for black coat, but if he is also homozygous for the recessive gene for albinism, the coat is white. This is known as recessive epistasis, since two genes for albinism must be present. In dominant epistasis, only one gene is necessary to cause the inhibition. In man there is a dominant gene for dwarfism (Chondrodystropic dwarfism) and a single gene for this condition can be epistatic to the genes for normal growth.

EPISTAXIS. Hemorrhage from the nose. **Nosebleed**.

EPITAXIS. The state or process wherein one crystalline material builds up a layer (usually thin) of its own crystal lattice upon the surface of some other crystal with a lattice geometry similar in crystal symmetry and lattice spacing to its own. Also called *oriented overgrowth*.

A close match of lattice geometry gives rise to ice nucleation, at only a few degrees below 0 °C (32 °F), whereas a small water drop may normally supercool some tens of degrees K. The effect has been demonstrated for water vapor growth to ice crystals and freezing of supercooled droplets on large single crystals, oriented with respect to the base common occurrence crystal such as silver iodide. Molecule size and structure also influence the effect.

EPITAXY. Oriented intergrowth between two solid phases. The surface of one crystal provides, through its lattice structure, preferred positions for the deposition of the second crystal.

EPITHELIUM. Tissue that covers surfaces and lines hollow organs, and the derivatives of these tissues, whether solid or hollow. All epithelial tissues are made up of closely associated cells with very little intercellular material and most of them have one surface free and the other connected with an underlying tissue.

Epithelia are classified according to the form of cells, the number of layers, and the embryonic origin and location. In flat, pavement, or squamous epithelium the cells are much thinner than their diameter. Cuboidal epithelium is made up of cells approximately as thick as their width. They are not strictly cubic but are polyhedral prisms. Columnar epithelium contains cells that are much higher than their diameter. Glandular epithelia are usually of the two latter forms. Any of these forms of cells may occur in more than one layer as a stratified epithelium, but flat epithelia are more often stratified and thicker cells usually form a single layer, or a simple epithelium. In some cases, the epithelium is made up of cells of several forms in two or three layers, which change movements of the part. Such a tissue is called traditional. Others appear to have several layers of cells but all are attached to the underlying tissue, rising to various heights. This is a pseudo-stratified epithelium.

According to origin and position, two kinds of epithelia derived from the mesoderm are recognized. Of these, endothelium lines the circulatory organs and mesothelium lines the body cavity. Other special types of epithelium are derived from each of the three germ layers. The free surfaces of some bear cilia.

The cells of many epithelia produce special secretions, and in some cases, these glandular layers are highly developed to form massive structures known as glands.

Most epithelia rest on a thin basement membrane or *membrana propria* derived from the connective tissues.

EPITOPES. Epitopes are three-dimensional structures on the surface of biological molecules that mediate specific recognition by the immune system. Since in a biological system antibody molecules face a virtually infinite number of structures, cognate interactions with epitopes are the basis of the primordial intelligence that drives the teleological choices of the immune system.

Biological macromolecules such as proteins, carbohydrates and lipids are assembled from a large number of chemical subunits. The permutational arrangement of these building blocks defines the sequence and the three-dimensional macromolecular structure. The unique surface architecture of a molecule is exploited by the immune system to recognize antigens both at the induction and the effector stage and to discriminate between self and nonself. The complementarities of surfaces are the basis of binding of molecules. The binding site on the antigen defines the epitope. Although technically this term, introduced by Jerne [1960] for antigens, could be applied to any interaction between molecules, it is mostly reserved for the recognition structures of antigens or antigenic determinants. In recent years, epitopes of numerous infectious agents, allergens, proteins that are involved in immune recognition including autoimmunity have been defined. Antigens are recognized by specific B or T cells in fundamentally different ways. See also **Antigen** and **Allergens**.

B-cell epitopes (BCE) are the recognition structures, antigenic determinants or binding sites of antibodies or B-cell receptors (surface immunoglobulins), on the surface of antigens. The antigen-binding site on the antibody, the paratope, recognizes antigens in their native, unprocessed, three-dimensional conformation [van Regenmortel, 1994].

While the B-cell receptor interacts with the native antigen, the T-cell receptor (TCR) recognizes the antigen only after processing by antigen-presenting cells (APCs) and in association with the major histocompatibility complex (MHC). Depending on the origin of the antigen, two distinct intracellular pathways generate antigenic peptides and target it either to the MHC class I or class II. Peptides from antigens that reach or are synthesized in the cytosol undergo proteolysis predominantly by the proteosome, translocate into the endoplasmic reticulum by transporters associated with antigen processing (TAP), where peptides colocalize and associate with MHC class I molecules [York and Rock, 1996]. These migrate to the cell surface and upon cognate interaction activate CD8+ cytotoxic T cells

(CTLs), these peptides and the resulting interactions are said to be class I-restricted and recognized by CD8+ T cells. Exogenous antigens that enter cells are proteolysed in the endocytic pathway and return to the cell surface as MHC class II-restricted peptides; these then activate antigen-specific CD4+ T-helper cells that in return activate B cells or macrophages that are unable to handle phagocytosed antigen load. The distinct but overlapping processing and presentation pathways for exogenous and endogenous antigen generate distinct sets of TCEs that reflect the necessity to encounter both types of antigens by different effector mechanisms. Extracellular antigen or pathogens are neutralized by antibody-based effector mechanisms and/or by macrophages, whereas intracellular pathogens are cleared by CTLs that kill infected cells. Most cells can be invaded by pathogens, which explains why the vast majority of cells can present MHC class I-restricted TCEs. In contrast, class II-restricted presentation of peptides is limited to antigen-presenting cells (dendritic cells, macrophages and B cells and some other activated cells) that provide this specialized immune function for the benefit of the whole organism.

EPIZOOTIC. Term descriptive of any disease in animals whose incidence and distribution resemble those of an epidemic in humans.

EPOCH (ASTRONOMY). In astronomy, an "epoch" is a moment in time for which celestial coordinates or orbital elements are specified. In the case of celestial coordinates, the position at other times can be computed by taking into account precession and proper motion. In the case of orbital elements, it is necessary to take account of perturbation by other bodies in order to calculate the orbital elements for a different time.

The currently used standard epoch is J2000.0, which is January 1, 2000 at 12:00 Terrestrial Time (TT). The prefix "J" indicates that it is a Julian epoch. The previous standard epoch was B1950.0, with the prefix "B" indicating it was a Besselian epoch.

EPOXY RESINS. A family of thermosetting resins known for their excellent mechanical and electrical properties, dimensional stability, resistance to high temperatures and numerous chemicals, and for their strong adhesion to glass, metal, fibers, and numerous other materials. Structurally, epoxy resins are characterized by the presence of a three-membered ring known as the epoxy, epoxide, oxirane, or ethoxylline group. The word "epoxy" is derived from the Greek prefix "ep," which means over and between, and "oxy," the combining form of oxygen. By strict definition, epoxy resins refer only to uncross-linked monomers or oligomers containing epoxy groups. However, in practice, the term epoxy resins is loosely used to include cured epoxy systems. It should be noted that very high molecular weight epoxy resins and cured epoxy resins contain very little or no epoxide groups. The vast majority of industrially important epoxy resins are bi- or multifunctional epoxides. The monofunctional epoxides are primarily used as reactive diluents, viscosity modifiers, or adhesion promoters, but they are included here because of their relevance in the field of epoxy polymers.

Epoxies are one of the most versatile classes of polymers with diverse applications such as metal can coatings, automotive primer, printed circuit boards, semiconductor encapsulants, adhesives, and aerospace composites. Most cured epoxy resins provide amorphous thermosets with excellent mechanical strength and toughness; outstanding chemical, moisture, and corrosion resistance; good thermal, adhesive, and electrical properties; no volatiles emission and low shrinkage upon cure; and dimensional stability — a unique combination of properties generally not found in any other plastic material. These superior performance characteristics, coupled with outstanding formulating versatility and reasonable costs, have gained epoxy resins wide acceptance as materials of choice for a multitude of bonding, structural, and protective coatings applications.

Commercial epoxy resins contain aliphatic, cycloaliphatic, or aromatic backbones and are available in a wide range of molecular weights from several hundreds to tens of thousands. The capability of the highly strained epoxy ring to react with a wide variety of curing agents under diverse conditions and temperatures imparts additional versatility to the epoxies. The major industrial utility of epoxy resins is in thermosetting applications. Treatment with curing agents gives insoluble and intractable thermoset polymers. In order to facilitate processing and modify cured resin properties, other constituents may be included in the compositions: fillers, solvents, diluents, plasticizers, accelerators, curatives, and tougheners.

Epoxy resins were first offered commercially in the late 1940s and are now used in a number of industries, often in demanding applications where their performance attributes are needed and their modestly high prices are justified. However, aromatic epoxies find limited uses in exterior applications because of their poor ultraviolet (UV) light resistance. Highly cross-linked epoxy thermosets sometimes suffer from brittleness and are often modified with tougheners for improved impact resistance.

The largest use of epoxy resins is in protective coatings (>50%), with the remainder being in structural applications such as printed circuit board (PCB) laminates, semiconductor encapsulants, and structural composites; tooling, molding, and casting; flooring; and adhesives. New, growing applications include lithographic inks and photoresists for the electronics industry.

Resin Properties

Epichlorohydrin and Bisphenol A-Derived Resins. The most widely used epoxy resins are diglycidyl ethers of bisphenol A (1) derived from bisphenol A and epichlorohydrin.

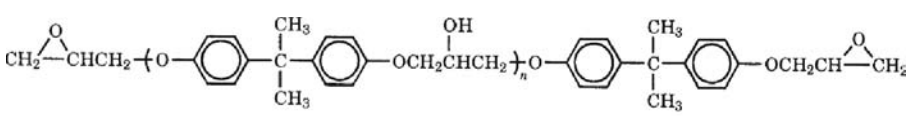
The outstanding performance characteristics of the resins are conveyed by the bisphenol A moiety (toughness, rigidity, and elevated temperature performance), the ether linkages (chemical resistance), and the hydroxyl and epoxy groups (adhesive properties and formulation latitude, or reactivity with a wide variety of chemical curing agents). See also **Phenolic Resins**.

The bisphenol A-derived epoxy resins are most frequently cured with anhydrides, aliphatic amines, or polyamides.

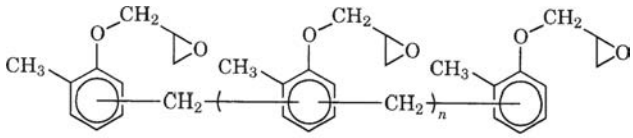
Diluents are commonly used to reduce the viscosity of epoxy systems to aid handling, improve ease of application, and to facilitate higher filler loading to reduce formulation cost. This, however, is achieved at the expense of other properties. To achieve a balance of properties, careful selection of diluent is needed.

Specialty Epoxy Resins. In addition to bisphenol, other polyols such as aliphatic glycols and novolaks are used to produce specialty resins. Epoxy resins may also include compounds based on aliphatic, cycloaliphatic, aromatic, and heterocyclic backbones. Glycidylation of active hydrogen-containing structures with epichlorohydrin and epoxidation of olefins with peracetic acid remain the important commercial procedures for introducing the oxirane group into various precursors of epoxy resins.

Epoxy Cresol–Novolak Resins (ECN). The cresol–novolak epoxy resins (2) are multifunctional, solid polymers characterized by low ionic and hydrolyzable chlorine impurities, high chemical resistance, and good thermal performance. ECN resins are widely used as base components in high performance electronic and structural molding compounds, high temperature adhesives, castings and laminating systems, tooling applications, and powder coatings.



(1)



(2)

The epoxy cresol–novolak resins (2) are prepared by glycidylation of *o*-cresol–formaldehyde condensates in the same manner as the phenol–novolak resins.

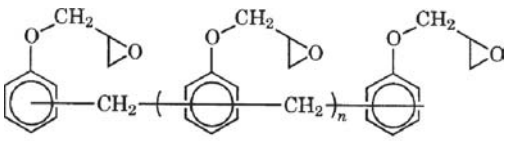
Bisphenol F Resin. Bisphenol F epoxy resin is of the same general structure as the epoxy phenol novolaks. Bisphenol F is 2,2′-methylene bisphenol.

Owing to relatively low viscosity, these resins offer advantages for 100% solids (solvent-free) systems. Higher filler levels are possible because of the low viscosity. Faster bubble release is also achieved. Higher epoxy content and functionality of bisphenol F epoxy resins can provide improved chemical resistance compared to conventional epoxies.

Bisphenol F epoxy resins are used in high-solids-high-build systems such as tank and pipe linings, industrial floors, road and bridge deck toppings, structural adhesives, grouts, coatings, and electrical varnishes. Bisphenol F epoxy resins are manufactured in Europe and Japan.

Epoxy Phenol–Novolak Resins. Epoxy phenol–novolak resins are represented by the general idealized structure (3) whereby multifunctional products are formed containing a phenolic hydroxyl group per phenyl ring in random para–para′, ortho–para′, and ortho–ortho′ combinations.

Subsequent epoxidation with epichlorohydrin yields the highly functional epoxy novolak. The product can range from a high viscosity liquid of $n = 0.2$ to a solid of n value greater than 3.



(3)

The thermal stability of epoxy phenol–novolak resins is useful in adhesives, structural and electrical laminates, coatings, castings, and encapsulations for elevated temperature service. Filament-wound pipe and storage tanks, liners for pumps and other chemical process equipment, and corrosion-resistant coatings are typical applications using the chemically resistant properties of epoxy novolak resins.

Curing agents that give the optimum in elevated temperature properties for epoxy novolaks are those with good high temperature performance such as aromatic amines, catalytic curing agents, phenolics, and some anhydrides.

Polynuclear Phenol–Glycidyl Ether-Derived Resins. This is one of the first commercially available polyfunctional products. Its polyfunctionality permits upgrading of thermal stability, chemical resistance, and electrical and mechanical properties of bisphenol A–epoxy systems. It is used in molding compounds and adhesives.

Cycloaliphatic Epoxy Resins. This family of aliphatic, low viscosity epoxy resins consists of two principal varieties, cycloolefins epoxidized with peracetic acid and diglycidyl esters of cyclic dicarboxylic acids.

The nonaromatic nature of these materials provides for improved uv resistance and arc-track resistance compared to conventional epoxies. The best properties are generally achieved with anhydride and phenolic curing agents.

Recommended applications include transformers, insulators, bushings, wire and cable coatings, generators, motors and switchgear, additives for adhesives, vinyl stabilization, and as viscosity depressants.

Aromatic and Heterocyclic Glycidyl Amine Resins. Among the specialty epoxy resins containing an aromatic amine backbone, the following are commercially significant.

Tetraglycidylmethylenedianiline-Derived Resins are made from aromatic glycidyl amines can be formulated into hot-melt or solution-binder systems with various reinforcements, e.g., glass, graphite, boron, or aramid. They are utilized for graphite-reinforced composites in aerospace and leisure products, structural adhesives, laminates, tooling and casting applications, and structures such as wings and fuselages.

Triglycidyl p-Aminophenol-Derived Resins are derived from triglycidyl *p*-aminophenol were originally developed by Union Carbide Corp., Synthesis is conducted by reaction of epichlorohydrin with the phenolic and amino groups followed by dehydrohalogenation. The product is a viscous liquid (15–5 Pa·s (15–50 P) at 25 °C) which is considerably more reactive toward amines than standard bisphenol A-derived resins.

Used to increase heat resistance and cure speed of bisphenol A epoxy resins, it has utility in such diverse applications as adhesives, tooling compounds, and laminating systems.

Triglycidyl isocyanurate is a solid resin that provides superior thermal, electrical, and mechanical properties and is recommended for laminates, insulating varnishes, coatings, and adhesives. Widely used as a curing agent for special polyester-based weatherable powder coatings, it is also used in electronic applications owing to its retention of optical transparency after aging at temperatures up to 150 °C and minimal smoke evolution on thermal decomposition (see EMBEDDING).

The triazine ring-containing product 1,3,5-triglycidyl isocyanurate is synthesized by glycidylation of cyanuric acid with epichlorohydrin.

Resin Synthesis and Manufacture

Epichlorohydrin and Bisphenol A-Derived Resins. Liquid epoxy resins may be synthesized by a two-step reaction of an excess of epichlorohydrin to bisphenol A in the presence of an alkaline catalyst. The reaction consists initially in the formation of the dichlorohydrin of bisphenol A and further reaction by dehydrohalogenation of the intermediate product with a stoichiometric quantity of alkali.

In recent years, production of liquid resins of higher purity, i.e., higher monomer content and fewer side-reactions, has been accomplished. This is in response to more stringent product quality requirements.

Aliphatic Glycidyl Ethers. Aliphatic epoxy resins have been synthesized by glycidylation of difunctional or polyfunctional polyols such as a 1,4-butanediol, 2,2-dimethyl-1,3-propanediol (neopentyl glycol), polypropylene glycols, glycerol, trimethylolpropane, and pentaerythritol.

The epoxidation is generally conducted in two steps: (1) the polyol is added to epichlorohydrin in the presence of a Lewis acid catalyst (stannic chloride, boron trifluoride) to produce the chlorohydrin intermediate, and (2) the intermediate is dehydrohalogenated with sodium hydroxide to yield the aliphatic glycidyl ether. Solid epoxy resins are prepared by the Taffy or Advancement processes.

Taffy Process. Bisphenol A reacts directly with epichlorohydrin in the presence of a stoichiometric amount of caustic. The molecular weight of the product is governed by the ratio of epichlorohydrin–bisphenol A. In practice, the taffy process is generally employed for only medium molecular-weight resins ($n = 1 - 4$).

Advancement Process. In the advancement process, sometimes referred to as the fusion method, liquid epoxy resin (crude diglycidyl ether of bisphenol A) is chain-extended with bisphenol A in the presence of a catalyst to yield higher polymerized products. The advancement process is more widely used in commercial practice.

In recent years, proprietary catalysts for advancement have been incorporated in precatalyzed liquid resins. Thus only the addition of bisphenol A is needed to produce solid epoxy resins. Use of the catalysts is claimed to provide resins free from branching which can occur in conventional fusion processes. Additionally, use of the catalysts results in rapid chain-extension reactions because of the high amount of heat generated in the processing.

The preparation of flame-retardant epoxy resins is accompanied by inclusion of tetrabromobisphenol A in the advancement process See also **Flame-Retarding Agents**. Products containing ca 20 wt% Br are extensively employed in the printed circuit board industry.

Liquid resins containing bromine (ca 49 wt%) can also be prepared directly from tetrabromobisphenol A and epichlorohydrin and are used for critical applications where a high degree of flame retardancy is required.

Curing Reactions

A variety of reagents has been described for converting the liquid and solid epoxy resins to the cured state, which is necessary for the development of

the inherent properties of the resins. Liquid epoxy resins contain mainly epoxy groups and solid resins are composed of both epoxy and hydroxyl curing sites. The curing agents or hardeners are categorized as either catalytic or coreactive and the functional groups of the resins are terminal epoxy together with a pendent hydroxyl per repeat unit of the polymer chain.

Health and Safety Factors

There have been many investigations of the toxicity of various classes of epoxy-containing materials (glycidyloxy compounds). The use and interpretation of the vast amount of data available has been obscured by two factors: (1) proper identification of the epoxy systems in question and (2) lack of meaningful classification of the epoxy materials. In general, the toxicity of many of the glycidyloxy derivatives is low but the diversity of compounds found within this group does not permit broad generalizations for the class.

Applications. Epoxy resins are used in protective coatings, e.g., waterborne coatings, high solids coatings, and powder coatings, structural composites, electrical laminates, electrical, electronics, and structural applications (molding components and casting and encapsulation), and adhesives.

EPPLEY PYRHELIOMETER. A pyrheliometer of the thermoelectric type. Radiation is allowed to fall on two concentric silver rings, the outer covered with magnesium oxide and the inner covered with lampblack. A system of thermocouples (thermopile) is used to measure the temperature difference between the rings. Attachments are provided so that measurements of direct and diffuse solar radiation may be obtained. This instrument has been adopted by the U.S. Weather Bureau for station use.

For instrumentation of NOAA's Surface Radiation Research Branch. See http://www.srrb.noaa.gov/instrument/instpage.htm

EPSOMITE. Epsomite is normally found as an efflorescence on mine and cave walls. It belongs to the orthorhombic crystal system, being a hydrous sulfate of magnesium, $MgSO_4 \cdot 7H_2O$, with vitreous to earthy luster and colorless to white, of transparent/translucent quality. Hardness of 2–2.5, and specific gravity of 1.68. It is very bitter to the taste. Found with the soluble salt lake deposits in Stassfurt, Germany, and in limestone caves in Kentucky, Tennessee and Indiana; also in several California and Colorado abandoned mines.

EQUAL-AREA MAP. A map so drawn that a square mile in one portion of the map is equal in size to a square mile in any other portion. This is obtained by changing the scales along the meridians and parallels in inverse proportion to each other.

Equal-area maps covering the whole globe, such as the Sanson-Flamsteed sinusoidal projection, are approximately elliptical. In Lambert's azimuthal equal-area projection, the parallels of latitude come closer together as the equator is approached (see also **Lambert Projection**). Any map from the center of the whole world or of a hemisphere necessarily distorts the shape of a region far from the center of the map, but such maps are useful for some climatological studies in which the correct representation of area is important. For limited parts of the globe, equal-area projections are quite practical. (Cf. **Conformal Map**. See also **Map Projections**.)

EQUAL-ENERGY SOURCE. A light source, for which the time rate of emission of energy per unit of wavelength is constant throughout the spectrum.

EQUALIZER (Network). It is very difficult to construct apparatus and particularly lines for communication circuits that will pass all the necessary frequencies equally. Often it is necessary to insert networks whose function is merely to restore the original relation of the various frequencies. These are called equalizers. Usually they are loss circuits which will cause more loss in those frequencies that had been attenuated less and the opposite for those attenuated the most. Thus the equalizer shows a frequency response which is the inverse of the system it is intended to equalize, so the result of connecting it in the circuit is to restore the overall response to a flat characteristic. Equalizers may be used to correct either frequency or distortion, or phase distortion, or all. The term equalizer is also used for the series of connections sometimes made in D.C. machines to insure equal current distribution in the conductors.

EQUATION. An equality involving two or more numbers or functions. Equations are classified by terms describing the functions in them or they are given the name of a mathematician who discovered or studied the equation. Depending on the functions, the equation could be algebraic or transcendental, with many subclasses in both of these types.

A plane curve is usually described by a single equation in two variables representing rectangular or polar coordinates. Sometimes it is preferable to represent the curve by parametric equations expressing the coordinates separately in terms of a third variable, the parameter. Parametric equations of surfaces and of curves in space are also useful.

The equation of a given locus is the equation that is satisfied by the coordinates of all points of this locus, and of only such points.

When it is of interest to find the solution of an equation, approximate methods are often useful.

EQUATION OF STATE. Also called *characteristic equation*, a relation, empirical or derived, between thermodynamic properties of a substance or system. The equation of state must be single-valued in terms of its variables. This is a direct consequence of the concept of state.

There exist systems, namely systems which undergo processes involving hysteresis (plastic deformation or ferromagnetism, for example) for which no equation of state can be indicated. Although the laws of thermodynamics may apply to such systems, the rigorous results of classical thermodynamics are not applicable because the science of thermodynamics is developed on the assumption of the existence of the single-valued function.

In the realm of classical thermodynamics, equations of state are assumed given. They can be derived from first principles only by the methods of statistical mechanics and quantum mechanics. These rely on the adoption of suitable molecular models for substances, and so far no universal, generally applicable model has been discovered even for narrow classes of substances such as gases.

It is an experimental fact that every thermodynamic system possesses a definite number n of independent properties that determine its state. Consequently, an equation of state is a relation between n properties (mutually independent) chosen (otherwise arbitrarily) as the independent properties $(x_1, x_2 \ldots x_n$ of the system and one more property, the dependent property y. Hence the equation of state is a function of the form

$$F(y, x_1, x_2, \ldots x_n) = 0$$

The simplest thermodynamic systems possess two independent properties, consequently the simplest equation of state is written in terms of three variables. When it is written in terms of pressure p, volume V, and absolute temperature T, it is called the p-V-T relation for the system or the thermal equation of state. When one of the caloric-thermodynamic properties (better called caloric properties, because p, V, T are thermodynamic properties also), such as enthalpy, entropy, Gibbs function, or work

function (Helmholtz function) are given, the equation is called a thermodynamic equation, or better, a caloric equation of state, although the latter is not a commonly accepted designation.

Even in the case of a simple system, one equation of state, e.g., the equation $f(p, V, T) = 0$, does not necessarily determine the form of all the other equations of state. This is connected with the fact that the derivation of the other equations of state may involve the integration of partial derivatives which leads to the appearance of whole functions in the integration "constant." An equation from which other equations of state can be derived by differentiation only, is called a *fundamental equation* (of state). In the case of a pure substance in a specified phase, the p, V, T relation does not constitute a fundamental equation with respect to the properties U, H, S, G, A, or their derived properties C_p, C_v, γ, etc. Consequently, it is possible to have two or more substances whose p, V, T relations are identical but whose specific heats, for example, are different.

In the case of continuous systems, for which the state changes from point to point(for example, a flow field of a viscous fluid), it is assumed that at every point, the equation of state is the same as for a homogeneous system and does not involve the gradients of the thermodynamic properties. Hence, such systems can only be studied with the aid of thermodynamics if local departures from equilibrium are small (near-equilibrium processes), i.e., if the gradients of the thermodynamic properties are not too great.

An equation of state must necessarily involve a finite (even if very large) number of independent variables. The particular variables which are chosen as independent is immaterial, on condition that they are mutually independent, and that their number is appropriate to the physical nature of the system.

Equations of states of various types of systems are numerous. The Curie equation is the equation of state of a paramagnetic solid. The Beattie and Bridgeman equation, Berthelot equation, Clausius equation, Dieterice equation, Keyes equation, and Van der Waals equation are other examples in this category.

It should be noted that equations of state for systems which consist of several components, rather than a single substance, can be written by introducing the variables $N_1, N_2, \ldots N_c$, which are the respective mole numbers of the components present.

EQUATION OF TIME. Prior to 1965, the difference between *mean time* and *apparent time*, usually labeled + or − as it is to be applied to mean time to obtain apparent time. After 1965, the correction to be applied to 12 hours + local mean time (LMT) to obtain the local hour angle (LHA) of the sun. See also **Time**.

EQUATOR. A plane perpendicular to the axis of rotation of the earth and passing through the center of the earth will intersect both the surface of the earth and the celestial sphere in great circles. These great circles are known as the terrestrial and celestial equators. Some navigators refer to the celestial equator as the equinoctial. See also **Thermal Equator**.

EQUATORIAL CLIMATE. See **Climate**.

EQUATORIAL COORDINATES (Astronomy). Equatorial coordinates are a system of spherical coordinates, in which the origin may be the eye of the observer (in which we have the apparent system of coordinates), the center of the earth (geocentric system), the center of the sun (heliocentric system), or the center of the Milky Way (galactocentric system). The fundamental line in the heliocentric system is the line joining the poles of rotation of the earth, which cuts the celestial sphere in its poles of rotation. The plane perpendicular to the fundamental line through the origin is the celestial equator. The fundamental direction in the plane may be either the point of intersection of the local meridian with the celestial equator, which is above the horizon, or the vernal equinox.

To locate an object in this system of coordinates, a plane is passed through the object and the line joining the poles of rotation, and this plane cuts out a great circle, known as an hour circle, on the celestial sphere perpendicular to the plane of the equator. The declination of an object is the angular distance of the object north (+) or south (−) of the celestial equator measured in the plane of the hour circle through the object. The hour angle of the object is the angular distance, measured in the plane of the equator, from the point of intersection of the meridian above the horizon to the point of intersection of the hour circle through the object, in the direction of apparent rotation (west) of the celestial sphere. The right ascension of the object is the angular distance, measured in the plane of the equator from the vernal equinox to the point of intersection of the hour circle in a direction (east) contrary to the direction of apparent rotation of the celestial sphere. For convenience, both right ascension and hour angle are frequently expressed in units of hour, minutes and seconds of time, rather than the more common angular notation of degrees, minutes, and seconds of arc.

Due to the fact that the local meridian remains fixed as the celestial sphere apparently rotates, the hour angle of an object is continually changing. Since both the vernal equinox and the hour circle rotate with the celestial sphere, both the right ascension and declination of the object remain fixed as the sphere rotates. However, both right ascension and declination change slowly due to precession and nutation. In tabulating these coordinates in star catalogues, the values are given for the position of the equinox for some particular date, and the corrections necessary to reduce the positions to the present date must be applied.

See also **Celestial Sphere and Astronomical Triangle**.

EQUATORIAL COUNTERCURRENT. A current moving eastwards and caused by the return of lighter water piled up on the inner margins by the North Equatorial Current and South Equatorial Current on the western side of the ocean basin. This countercurrent lies in a band of calm air, the doldrums. See also **Winds and Air Movement**.

EQUATORIAL CURRENT SYSTEM. See **Ocean Currents**.

EQUATORIAL DEEP JETS. See **Ocean Currents**.

EQUATORIAL TELESCOPE. A telescope so mounted that it may be moved parallel to the equatorial coordinates of hour angle and declination; sometimes called simply an equatorial. In this form of mounting, one axis, known as the polar axis, is parallel to the axis of rotation of the earth, and the other axis, known as the declination axis about which the telescope may be rotated, is perpendicular to the polar axis. From this arrangement of the axes, the telescope as it is rotated about the declination axis, must move in a plane perpendicular to the equator, and hence, parallel to hour circle or in the direction of declination. The rotation of the declination axis about the polar axis, with the telescope remaining fixed in declination, will cause the telescope to move parallel to the equator, and hence, in the coordinate of hour angle.

The majority of equatorials are carried on a single pier. The difficulty with this form of mounting is that the telescope will frequently run into the pier when the hour angle is close to zero. To avoid this, several other methods of supporting the polar axis have been devised. Perhaps the most common is the so-called English mounting, in which the two ends of the polar axis are supported on separate piers, with the telescope free to pass through zero hour angle.

The most difficult adjustment of the equatorial is to get the polar axis strictly parallel to the axis of rotation of the earth. When this has been accomplished, the instrument is by far the most convenient of all forms of mounting. If the instrument is rotated about the polar axis from east to west at exactly the same rate that the earth is rotating about its axis from west to east, the telescope lens will remain fixed relative to objects on the celestial sphere. Hence, once the instrument is set on a star, clockwork may be devised to keep the telescope "following."

EQUATORIAL TROUGH. See **Meteorology**.

EQUATORIAL UNDERCURRENT (EUC). See **Ocean Currents**.

EQUATORIAL UPWELLING. The rising of water along the equator from about 200 meters (656 feet) to the surface. It occurs in the Atlantic and Pacific Oceans where the Southern Hemisphere trade winds reach into the Northern Hemisphere, giving uniform wind direction on either side of the equator. Because the surface currents of the Ekman spiral are deflected to different sides of the wind in both hemispheres, the surface water is

drawn away from the equator, causing the colder water from deeper layers to upwell.

EQUATORIAL WATER. The water mass of the permanent or oceanic thermocline (100–600 meters (328–1,969 feet) in the tropical Pacific from 20°S to 15°N. South Pacific Equatorial Water (SPEW) occupies the region south of the equator; it is derived from central water and an injection of high-salinity water formed by evaporation near Polynesia that sinks to a depth of 200 meters (656 feet). North Pacific Equatorial Water (NPEW) is found north of the equator; it is formed by subsurface mixing between SPEW and central water. Indian Central Water is a historical term used for Australasian Mediterranean Water in the western Indian Ocean before the Indonesian Seas were recognized as its source region.

EQUATORIAL WESTERLIES. See **Winds and Air Movement**.

EQUATOR-S MISSION. See **Space Science Missions: Sun**.

EQUILIBRIUM. In the elementary sense of the macroscopic (visible to the naked eye) system, equilibrium is obtained if the system does not tend to undergo any further change of its own accord.

Mechanical and Electromagnetic Systems. Equilibrium in mechanical and/or electromagnetic systems is reached when the vectorial summation of generalized forces applied to the system is equal to zero. In any potential field, that is, gravitational or electric vector potential, force can be expressed as gradient of potential (magnetic force however, is a curl of a vector potential). The potential energy therefore has an extremum at the equilibrium configuration. For example, a system such as a mass suspended by a string against the gravitational force (or its weight) is at mechanical equilibrium if the tensile force in the string is equal to the weight of the mass it supports. The d'Alembert principle further states that the condition for equilibrium of a system is that the virtual work of the applied forces vanishes.

Thermodynamic Systems. When a hot body and a cold body are brought into physical contact, they tend to achieve the same warmth after a long time. These two bodies are then said to be at thermal equilibrium with each other. The zeroth law of thermodynamics (R.H. Fowler) states that two bodies individually at equilibrium with a third are at equilibrium with each other. This led to the comparison of the states of thermal equilibrium of two bodies in terms of a third body called a thermometer. The temperature scale is a measure of state of thermal equilibrium, and two systems at thermal equilibrium must have the same temperature.

Generalization of equilibrium consideration by the second law of thermodynamics specifies that the state of thermodynamic equilibrium of a system is characterized by the attainment of the maximum of its entropy. Thermodynamic coordinates are defined in terms of equilibrium states.

Equilibrium between two phases of a system is reached when there is no net transfer of mass or energy between the phases. Phase equilibrium is determined by the equality of the Gibbs functions (also called free enthalpy, free energy, or chemical potential) of the phases in addition to equality of their temperatures and stresses (such as pressure and/or field intensities — intensive properties). Equilibrium of first-order phase change requires continuity of slope or first derivative of the Gibbs function with respect to an intensive property and is generalized as the Clapeyron relation. Second- and higher-order phase changes are given by the condition of continuity of curvature or second derivative of the Gibbs function and so on.

Chemical or nuclear equilibrium of a reactive system is reached when there is no net transfer of mass and/or energy between the components of a system. At chemical or nuclear equilibrium, the Gibbs function of the reactants and the products must be equal according to stoichiometric proportions, in addition to uniformity in temperature and stresses. Chemical equilibrium is summarized in the form of the Law of Mass Action. The trend for the displacement from an equilibrium state is specified by LeChâtelier's principle.

Thermodynamic equilibrium is reached when the condition of mechanical, electromagnetic, thermal, phase, and chemical and nuclear equilibrium is reached.

Stability of Equilibrium. A process or change of state carried out on a system such that it is always near a state of equilibrium is called a quasi-stationary equilibrium. This requires that the process be carried out slowly. If a mechanical system is initially at the equilibrium position with zero initial velocity, then the system will continue at equilibrium indefinitely. An equilibrium position is said to be stable if a small disturbance of the system from equilibrium results only in small, bounded motion about the rest position. The equilibrium is unstable if an infinitesimal displacement produces unbounded motion. In the gravitational field, a marble at rest in the bottom of a bowl is in stable equilibrium, but an egg standing on its end is in unstable equilibrium. When motion can occur about an equilibrium position without disturbing the equilibrium, the system is in neutral (or labile, or indifferent) equilibrium, an example being a marble resting on a perfectly flat plane normal to the direction of gravity. It is readily seen that stable equilibrium is the case when the extremum of potential is a minimum.

When dealing with general thermodynamic systems, the fact that entropy tends to a maximum in the trend toward equilibrium of a natural process generalizes the above mechanical consideration with respect to stability. An equilibrium state can be characterized as a stable equilibrium when the entropy is a maximum; neutral equilibrium when displacement from one equilibrium state to another does not involve changing entropy; and unstable equilibrium when entropy is a minimum. Any slight disturbance from an unstable equilibrium state of a system will lead to transition to another state of equilibrium.

Statistical Equilibrium. In the microscopic sense, that is, treating systems in terms of elemental particles such as molecules, atoms, and other material or quasi-particles (such as photons in radiation, phonons in solids and liquids), equilibrium states are recognized as the most probable states. An equilibrium state of a system is therefore defined in terms of most probable distributions of its elements among microscopic states which may be defined in terms of energy states. In this sense, statistical equilibrium is a condition for macroscopic equilibrium and an equilibrium state of a system is one of its extremal states. In the methods of statistical mechanics, the probability of distribution is expressed in terms of the density of distributions in the phase space. Based on the Liouville theorem, if a system is in statistical equilibrium, the number of the elements in a given state must be constant in time; which is to say that the density of distribution at a given location in phase space does not change with time. For an isolated system, the distribution is represented by a microcanonical ensemble. At equilibrium, no phase point can cross over a surface of constant energy, and the density of distribution is preserved. In this case individual molecules of a system can be represented by phase points. Any part of an isolated system in statistical equilibrium can be represented by a canonical ensemble. A subsystem of a large system in thermal equilibrium also behaves like the average system of a canonical ensemble. A system and a constant temperature bath together can be considered as an isolated system. A phase point in a canonical ensemble can represent a large number of molecules, thus accounting for strong interactions. A canonical ensemble is characterized by its temperature and is therefore pertinent to the concept of thermal equilibrium. When applied to equilibrium of systems involving mass exchange, such as a chemical system, we have a "particle bath" in addition to a constant temperature bath. The pertinent representation for equilibrium including mass exchange as well as energy exchange is known as a grand canonical ensemble, which accounts for the chemical potentials of its elements.

When applied to a system with a large number of elements, the distributions are measured by thermodynamic probability (W); the most probable distribution is such that W is a maximum. This optimal principle is consistent with the condition of maximum entropy (S) cited under **Entropy**. The Boltzmann hypothesis states that $S = k \ln W$, where k is the Boltzmann constant.

Depending on the specifications of W, namely, those of Maxwell-Boltzmann (for low concentration of distinguishable particles, weak interaction and high temperature, such as a dilute perfect gas), Fermi-Dirac (for elemental particles with antisymmetric wave functions at high concentrations of indistinguishable particles and low temperatures, such as electrons in metal), or Einstein-Bose (for elemental particles with symmetric wave functions, such as He^4 at high concentration of indistinguishable particles and low temperature), equilibrium distributions take different forms. The Maxwellian speed distribution in a dilute perfect gas is a distribution based on Maxwell-Boltzmann statistics.

As a consequence of molecular considerations, when two systems are connected for transfer of mass without significant transfer of energy, such as two containers at different temperatures connected by a capillary tube, we have the relation of thermal transpiration.

Trend toward Equilibrium. The mechanism by which equilibrium is attained can only be visualized in terms of microscopic theories. In the kinetic sense, equilibrium is reached in a gas when collisions among molecules redistribute the velocities (or kinetic energies) of each molecule until a Maxwellian distribution is reached for the whole bulk. In the case of the trend toward equilibrium for two solid bodies brought into physical contact, we visualize the transfer of energy by means of free electrons and phonons (lattice vibrations).

The Boltzmann H-theorem generalizes the condition that with a state of a system represented by its distribution function f, a quantity H, defined as the statistical average of $\ln f$, approaches a minimum when equilibrium is reached. This conforms to the Boltzmann hypothesis of distribution in the above in that $S = -\mathrm{kH}$ accounts for equilibrium as a consequence of collisions which change the distribution toward that of equilibrium conditions.

Consideration of perturbation from an equilibrium state leads to methods for dealing with rate processes and methods of irreversible thermodynamics in general.

Fluctuation from Equilibrium. A necessary consequence of the random nature of elemental particles in a body is that the property of such a body is not at every instant equal to its average value but fluctuates about this average. A precise meaning of equilibrium can only be attained from consideration of the nature of such fluctuations. In the above, we have repeatedly considered a "large" number of particles. It is important to know how large a number is "large." When considering fluctuation of energy from an average value in an isolated system, the ratio of the two is given to be proportional to $1/\sqrt{N}$, where N is the total number of elements in the system. This is also the magnitude of the fluctuation of number of particles in a system involving transformation of phases and chemical and nuclear species. An equilibrium state is one at which the longtime mean magnitude of fluctuation from the average state is independent of time and this magnitude has reached a minimum value.

Large perturbation from a given state of fluctuation leads to a relaxation process toward a state of equilibrium. The relaxation time, for instance, measures the deviation from quasistationary equilibrium of a process carried out at a finite rate.

EQUILIBRIUM CLIMATE. See **Climate**.

EQUILIBRIUM DIAGRAM. A diagram showing the phase fields of an alloy system under the conditions of complete equilibrium using as coordinates the temperature, the compositions in terms of the components, and the pressure. The most frequently used equilibrium diagrams in metallurgy are drawn with the pressure considered constant. See iron-carbon diagram under **Iron Metals, Alloys, and Steels**. See also **Distillation**.

EQUILIBRIUM VAPOR PRESSURE. The pressure of a vapor in equilibrium with its condensed phase (liquid or solid). This equilibrium is dynamic in that evaporation and condensation are both occurring but are in equilibrium. It is a function of temperature only and is nearly independent of the existence or density of other gases in a system. It may, however, be dependent on the shape of the surface of the condensed phase. More generally, the equilibrium vapor pressure with respect to small droplets containing soluble impurities may be quite different from the saturation vapor pressure.

See also **Saturation Vapor Pressure**.

AMS

EQUINES. See **Horses, Asses, and Zebras**.

EQUINOCTIAL RAINS. Rainy seasons that occur regularly in many places within a few degrees of the equator at or shortly after the equinoxes. This characteristic of two distinct annual precipitation maxima is found chiefly within a tropical rain forest climate. The main regions are the Congo Valley, the greater Amazon Valley, and the East Indies. In most places, the spring maximum is the greater.

EQUINOCTIAL STORM. Severe storms in the United Kingdom and North America that are popularly believed to accompany the vernal and autumnal equinoxes. The belief may have originated in the mid-1700s when sailors observed the West Indian hurricanes, which are most frequent at about the autumnal equinox. Statistics of gale frequency do not show that storms are especially frequent in temperate latitudes about 22 September, though it does sometimes happen that the first severe storm of the winter half-year occurs toward the end of September. The belief has been extended by analogy to the vernal equinox, about 21 March.

EQUINOX. The line of intersection of the plane of the earth's equator with the plane of the ecliptic (the line of nodes of the earth) intersects the celestial sphere in two diametrically opposite points known as the equinoxes. As seen from the earth, the sun apparently passes through each of the equinoxes once each year, passing through the vernal equinox on approximately March 21st and through the autumnal equinox on approximately September 22nd.

The great circle passing about the celestial sphere through the equinoxes and the pole of the ecliptic is known as the *equinoctial colure*.

The *autumnal equinox*, for either hemisphere, is the equinox at which the sun "retreats" into the opposite hemisphere. In northern latitudes, the time of this occurrence is approximately September 22nd. The *vernal equinox*, for either hemisphere, is the equinox at which the sun approaches from the opposite hemisphere. In northern latitudes, this occurs approximately on March 21st. See also **Celestial Sphere and Astronomical Triangle**.

EQUIVALENCE PRINCIPLE. It is always possible at a point in space-time to transform to a (in general accelerated) coordinate system such that the effects of gravity will disappear over a differential region in the neighborhood of the point. As a particular case, if there are two observers, one uniformly accelerated with acceleration g and not in a gravitational field, the other not accelerated but held in a uniform gravitational field g, the results of mechanical and optical experiments performed by the two observers will be identical. See also **Gravitation**; and **Relativity and Relativity Theory**.

EQUIVALENCE THEOREM. The field in a source-free region bounded by a surface could be produced by a distribution of electric and magnetic currents on that surface that would be equivalent, for points inside the surface, to the actual external sources.

EQUIVALENT BAROTROPIC MODEL. An enhanced form of barotropic model in which the variation of wind with height is vertically averaged assuming that the thermal wind is in the same direction as the geostrophic wind at all heights.

The resulting single-parameter model for geostrophic streamfunction is

$$\frac{\partial \nabla^2 \psi^*}{\partial t} + \mathbf{V}^* \cdot \nabla \left(\nabla^2 \psi^* + f + \frac{A(p_0) f_0 g}{R T_0} H \right) = 0,$$

which resembles the barotropic vorticity equation except for the third term inside the brackets. ψ^* and $\mathbf{V}^*$ are the vertically averaged geostrophic streamfunction and geostrophic wind, respectively. The coefficients p_0,

f_0, T_0, g, and R are customary parameters and are defined at a reference latitude at the lower boundary. A is a vertical averaging coefficient also defined at the lower boundary. H is the terrain height, allowing the equivalent barotropic model to represent orographic forcing in a crude way. This makes the equivalent barotropic model the most popular barotropic model for real data numerical forecasts. See also **Barotropic Model**; **Barotropic Vorticity Equation**; **Orographic**; and **Streamfunction**.

AMS

EQUIVALENT CIRCUIT. This term is applied to an electrical circuit that is electrically equivalent to another circuit, or sometimes, to a mechanical device. Equivalent circuits of mechanical systems or electromechanical systems such as loudspeakers enable the designer to apply methods of circuit analysis and often obtain a solution easily which would be very difficult if not impossible otherwise. The equivalent circuit method is used extensively in the analysis of communication circuits, particularly those involving vacuum tubes and transistors. These circuits do not yield the static currents and voltages (those existing in the absence of applied signals) but their use provides a method of computing the response to alternating voltages or dc changes, provided both are of small magnitude. Both of these are usually the ones of interest. Similarly, many other types of electrical circuits may be simplified in terms of equivalent circuits, sometimes giving all the necessary solutions, sometimes giving solutions for limited conditions, but, in most cases, greatly decreasing the labor involved in analyzing the circuit or equipment.

AMS

EQUIVALENT ELECTRONS. For an atom, electrons in the same orbital (whereby they have the same principal quantum number and the same azimuthal quantum number). For a molecule, electrons having the same quantum numbers, apart from spin, and the same symmetry g or u.

EQUIVALENT POTENTIAL TEMPERATURE. A thermodynamic quantity, with its natural logarithm proportional to the entropy of moist air, that is conserved in a reversible moist adiabatic process. Also called *wet-equivalent potential temperature*.

It is given most accurately as

$$\theta_c = T\left(\frac{p_o}{p_d}\right)^{R_d/(c_{pd}+r_s c)^H - r_s R_r/(c_{pd}+rsc)} \exp\left[\frac{L_S r_d}{(c_{pd}+r_s c)T}\right],$$

where θ_e is the equivalent potential temperature, c_{pd} is the heat capacity at constant pressure of dry air, r_t is the total water mixing ratio, c is the heat capacity of liquid water, T is the temperature, R_d is the gas constant for dry air, p_d is the partial pressure of dry air, p_0 is a reference pressure (usually 100 kPa), L_v is the latent heat of vaporization, r_v is the vapor mixing ratio, R_v is the gas constant for water vapor, and H is the relative humidity. Neglect of the quantity $r_t c$, where it appears, yields a simpler expression with good accuracy.

AMS

EQUIVALENT TEMPERATURE. 1. *Isobaric equivalent temperature*; the temperature that an air parcel would have if all water vapor were condensed out at constant pressure, the latent heat released being used to heat the air,

$$T_{i,e} = T[1 + (Lw/c_p T)]$$

where $T_{i,e}$ is the isobaric equivalent temperature; T is the temperature; w is the mixing ratio; L is the latent heat; and c_p is the specific heat of air at constant pressure.

2. *Adiabatic equivalent temperature*; the temperature that an air parcel would have after undergoing the following (physically unrealizable) process: dry-adiabatic expansion until saturated; pseudoadiabatic expansion until all moisture is precipitated out; dry-adiabatic compression to the initial pressure. This is the equivalent temperature as read from a thermodynamic chart and is always greater than the isobaric equivalent temperature:

$$T_{a,e} = T\exp(Lw/c_p T)$$

where $T_{a,e}$ is the adiabatic equivalent temperature. Also called *pseudoequivalent temperature*.

AMS

EQUIVOCATION. A measure of the average ambiguity of a received signal. It is the residual remaining uncertainty when the received signal has been interpreted.

ERA (Geology). See **Geologic Time Scale**.

ERBIUM[1]. [CAS: 7440-57-0] Chemical element symbol Er, at. no. 68, at. wt. 167.26, eleventh in the Lanthanide Series in the periodic table, mp 1529 °C, bp 2868 °C, density 9.066 g/cm^3 (20 °C). Elemental erbium has a close-packed hexagonal crystal structure at 25 °C. The pure metallic erbium is silver-gray in color and retains its luster at room temperature, not affected by moisture or normal atmospheric gases. Large pieces of the metal do not oxidize readily even when heated. Fine chips and powder, however, will ignite and burn. Because of its comparative softness, the metal can be worked by conventional equipment. The metal should be annealed after size-reduction. There are six natural isotopes ^{162}Er, ^{164}Er, ^{166}Er through ^{168}Er and ^{170}Er. Twelve artificial isotopes have been prepared. The natural isotopes are not radioactive. In terms of abundance, erbium is present on the average of 2.8 ppm in the earth's crust, making its potential availability about equal with uranium. The element was first identified by C.G. Mosander in 1843. The thermal-neutron-absorption cross section of erbium is 160 borns per atom, relatively high and tenth among the natural elements. The metal has a low acute-toxicity rating. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{11} 5s^2 5p^6 5d^1 6s^2.$$

First ionization potential 6.10 eV; second 11.93 eV. Ionic radius Er^{3+} 0.881 Å. Metallic radius 1.758 Å. Other important physical properties of erbium are given under **Rare-Earth Elements and Metals**.

Erbium occurs in certain types of apatites, xenotime, and gadolinite. These minerals also are processed for their yttrium content as well as for other heavy *Lanthanide* elements. With liquid-liquid organic and solid-resin organic ion-exchange techniques, the separation of erbium from the other elements is favorable.

Because of the metal's high thermal-neutron-absorption cross section, it has been of much interest in terms of use in nuclear reactor hardware. When an erbium-activated phosphor is coated onto a gallium-arsenide diode, the latter emits infrared radiation, which is converted to visible light by the phosphor. Through variation of the energizing power and by use of a combination of rare-earth-activated phosphors, the primary colors of light can be produced. Thus, erbium holds promise for use in display panels and color-television picture tubes. An erbium hydride-hydrogen system at a fixed temperature creates an extreme vacuum and when used for comparative purposes makes it possible to measure vacuums in the range of 10^{-4} to 10^{-11} torr with much precision. The system has been used for the calibration of ionization gauges used for very high vacuums as found in outer space. Erbium is in an early stage of investigation for application to lasers, semiconductor devices, garnet microwave devices, ferrite bubble devices, and catalysts.

See references listed at ends of entries on **Chemical Elements**; and **Rare-Earth Elements and Metals**.

Erbium in Lightwave Communication Amplifier. In January 1992, E. Desurvire (Columbia University Center for Telecommunications Research) reported that optical fibers made from silica glass and traces of erbium can amplify light signals when they are energized by infrared radiation. Desurvire developed an efficient radiation source (referred to as a laser diode chip) that, when integrated into a fiber optic communication system, can increase transmission capacity by a factor of 100.

The device can be effective in very long stretches of communication cable, such as used in transoceanic service. Each cable will be capable of carrying 500,000 messages simultaneously, a factor of 12 times greater than present cables.

[1] The main portion of this article was revised and updated by K.A. Gschneidner, Jr., Director, and B. Evans, Assistant Chemist, Rare-Earth Information Center, Energy and Mineral Resources Institute, Iowa State Univ., Ames, Iowa.

ERGODICITY. Generally, this word denotes a property of certain systems that develop through time according to probabilistic laws. Under certain circumstances a system will tend in probability to a limiting form independent of the initial position from which it started. This is the *ergodic property*. A stationary stochastic process (x_t) may be regarded as the set of all realizations possible under the process. Each such realization may have a mean m_r. If the process itself has a mean $E(x_t) = \mu$, the ergodic theorem of Birkhoff and Khintchine states that m_r exists for almost all realizations. If, in addition, $m_r = \mu$ for almost all realizations the process is said to be ergodic. In this sense ergodicity may be regarded as a form of the law of large numbers applied to stationary processes.

ERGOT. A fungus that grows upon and replaces the grain of rye. Ergot in the human body contracts smaller arteries and smooth muscle fibers, especially that of the uterus. Ergotism is a diseased condition of humans and domestic animals resulting from eating grasses or grain infected with ergot fungus; or from excessive uses of the drug made from the fungus. Ergotamine, one of the alkaloids of ergot, has been used in the treatment of migraine.

ERG. See **Units and Standards**.

ERIDANUS. A very long constellation that extends from the equator to the southern horizon. The constellation contains the star Achernar.

ERMINE. See **Mustelines**.

ERNST, RICHARD R. (1933–). A native of Switzerland who won the Nobel Prize in chemistry in 1991 for important methodological developments in NMR spectroscopy. He invented Fourier-transform NMR (FT-NMR), which multiplied sensitivity 10 to 100 times compared to dispersive instruments. He also devised two-dimensional NMR techniques, increasing resolution and enabling structure determinations of biologically important macromolecules. Ernst received his Ph.D from the Federal Technical Institute (ETH) in Zurich, Switzerland.

EROSION (Geology). A fundamental process of geology; it brings about alterations in rocks and other major features of the physical earth. Some of the results of erosion are beneficial, as exemplified by the gradual disintegration, transformation, and transportation of certain kinds of rocks to form soil. On the other hand, erosive processes can leach out or carry away excellent soil, and thus destroy agricultural productivity, sometimes over wide areas, by the action of wind and water. For soil erosion, see also **Soil**.

In a general sense, erosion refers to the reduction of the land surface toward sea level by the various agencies of weathering, stream action, glacial action, wind action, chemical action, and other forces. A majority of these forces occur naturally and essentially are beyond control by way of human intervention. On the other hand, erosion also results from unplanned (in terms of long-term) erosion by various projects which may create or accelerate already existing natural erosive processes. Alteration of the course of streams and certain types of agricultural methods can cause serious erosion problems.

The surface of the earth, subject to both natural and artificial forces, is constantly undergoing an overall process that may be termed *weathering*. Erosion is a major result of this process. Erosion processes may be classified into two major groups: (1) *chemical erosion*; and (2) *mechanical erosion*. The actions of erosive agents, such as air, wind, and water, may act both in a chemical and mechanical fashion. See also **Glacier**.

Chemical Erosion

The principal agents of chemical erosion are water and air. Both agents attack the content of the original rocks and thus bring about changes in chemical composition with accompanying physical changes. In falling through the atmosphere, rain water (*meteoric water*) picks up small amounts of oxygen, carbon dioxide, and other gases (notably in areas where air pollutants are present). The addition of these ingredients to otherwise pure water increases the solvent power of the water. Water in soaking downward through the soil reaches rocks which often contain numerous cracks and fissures, thus affecting the rock to cause a considerable area of exposed surface. Further, the solvent power of the water may be increased as it acquires new chemical substances from the rocks themselves. For example, water, attacking pyrite, will pick up sulfur and through a complex process ultimately convert this to sulfuric acid, which is highly corrosive. Particularly, the action of oxygen in the air combined with moisture from rain can become highly corrosive, as witness the immediate formation of rust upon exposed iron (ferrous) materials. Water plus carbon dioxide can yield corrosive carbonic acid. Thus, in processes of oxidation and carbonation, the chemical weathering of rocks is both erosive and corrosive. Water alone through the process of hydration can cause decomposition of some rocks. For example, two parts of hematite, Fe_2O_3, will unite with three parts of water to form limonite (iron rust), $2Fe_2O_3 \cdot 3H_2O$.

The erosive results of groundwater are principally chemical in nature. Although the corrosive solutions may move slowly, over periods of time extensive changes in rock structures can be brought about, particularly the creation of a large thickness of mantle rock. Thus, enormous caverns may be created, such as the Carlsbad Cave (New Mexico) or the Mammoth Cave (Kentucky). Also, rich ore deposits may result from such actions, as witness the great copper deposits found in the western United States or the iron deposits of the Lake Superior region. The analysis of ground waters testifies to their prior erosive performance. In descending order of content, groundwater will be found to contain: (1) calcium carbonate and calcium sulfate; (2) colloidal silica; (3) sodium carbonate, sodium sulfate, and sodium chloride; (4) magnesium carbonate; and (5) potassium carbonate. All of these materials are derived from prior contacts with rocks and soil. To a lesser extent, ocean water also works in a similar fashion along the coasts.

Mechanical Erosion

The mechanical effects of groundwater become significant when the volume and velocity of the water reach a point where the flow can pick up and transport solid particles of rock. Sometimes this process follows or is concurrent with the aforementioned chemical actions of groundwater. The lower portion of Mammoth Cave, exhibiting gravels, sands, and muds, provides evidence of the extensive action of groundwater. The principal results of the mechanical action of groundwater that may be observed from the surface include soil creep, landslides, and rock streams. The underlying slippery nature of shales and clays when wet assist the process of alteration. There are rock streams in the Rocky Mountains of the United States a mile or more in length. So-called "walking mountains" (as reported in China) are the result of such phenomena on an extremely large scale. See also **Cave**.

The mechanical actions of the oceans are far more important than their chemical actions in terms of erosion. These include the actions of waves, currents, and tides. A *terrace* or *wave-cut beach* is formed by the action of waves cutting into a land surface of moderate relief. A *sea-cliff* may result where relatively high land is undercut by waves. The chalk cliffs of England and France are examples. Where particularly soft, vulnerable rock structures are encountered by wave action, *sea caves* may be formed. The Blue Grotto (Naples) is a notable example. Sometimes spouting caves are formed. See also **Blowhole**. Where rocks contain vertical joints, these may be eroded at a greater rate, producing a cliff with deep indentations. Where the eroded rock may become separated from the land mass, it may form a *chimney* or *stack*. See also **Chimney Rock**. Where there is a rock connection remaining at a higher elevation, a *natural bridge* will be the result.

Waves of the oceans also may form deposits along the shore, built from the deposition of materials by the mechanical work of the waves. Such terms as *wave-built terraces*, *barrier beaches*, *spits*, *hooks*, *bars*, and *tombolos* are used to describe these resulting features. See also **Barrier Beach**.

The wind also serves as a mechanical agent for picking up, carrying, and later depositing solid materials. Numerous erosive features result. Wind-worn pebbles (glyptoliths) give evidence of wind erosion. These are also referred to as dreikanters. See also **Dreikanter**. The ravages of wind removal and transportation of soil are only too evident in certain dust bowl areas, generally the result of poor agricultural methods.

When material is moved by wind and ultimately released, two dominant types of deposits occur: (1) *loess*; and (2) *dunes*. See also **Dune**. Loess is composed of dust and silt, usually comprised of quartz grains, ranging in size from about 0.1 millimeter, and clay. Loess is characterized by

a buff-to-yellow color and great porosity. Loess may be observed along both sides of the Mississippi River (Louisiana and Mississippi, north Illinois and Iowa); also the Missouri River and other tributaries in the Mississippi Valley. Loess occurs extensively in central Europe and in Tibet, Mongolia, and China. Thicknesses of loess deposits in China up to 300 feet (91 meters) are reported. The deposits in Europe are usually quite thin; those in the United States range from 10 to 20 feet (3 to 6 meters) in thickness.

The particle size of sand in sand dunes ranges in diameter from 0.05 millimeter up to the size of coarse gravel. Most dunes are made up of quartz, but gypsum dunes are found in New Mexico. Dunes of calcareous oolites are found in the Bahamas and Bermuda; rather low dunes of dry clay occur in Montana.

Although of a seasonal nature, snow drifts are an aspect of the dune phenomenon.

Dunes range from a few feet to over 400 feet (120 meters) in height. They may cover a few square feet (a fraction of a square meter) to up to several square miles (kilometers). The dunes in desert regions commonly are 200 to 400 feet (60 to 122 meters) in height. Usually the axis of a dune is at right angles to the prevailing wind. Nearly all sand dunes migrate to a measurable extent unless they are covered with vegetation. Migrating dunes will advance upon forests, farms, highways. Dunes buried a number of cities of ancient times (Babylonian, Chaldean). Migration of dunes can be slowed or stopped through the planting of surface grasses and shrubs of a type that will withstand the prevailing climate.

The carrying of volcanic dust is a special form of wind deposit. Such deposits may occur long distances from their sources, as witness the volcanic dust deposits in southern Nebraska and north central Kansas.

Cycle of Erosion

This is a term used to generally describe the work of rivers and streams — erosional, transportational, and depositional. The erosional work of rivers and streams sculptures the surface of the earth into a variety of forms. The river erosion pattern of any region will depend upon the climate, the relative hardness and solubility of the formations, the structure, and the degree to which the erosive process has completed its work, with or without interruptions caused by diastrophism. The stream pattern of a region is not only indicative of the structural control, but also of the stage in its erosional history. The ideal complete cycle of erosion begins with uplift of a region with low altitude and ends with reduction of the uplifted region to a peneplain. See Fig. 1.

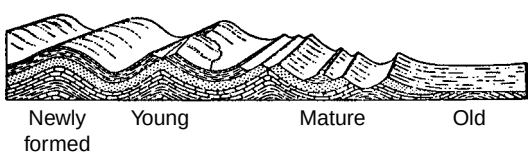

Fig. 1. Successive stages in the normal cycle of erosion in a region of folded rocks.

Soil Conservation through Erosion Control

Modern programs of erosion control have been organized on a large scale in the United States, Australia, New Zealand, and in several countries in Africa, south of the Sahara. In nearly all countries where agriculture is important, there has been recognition of the problem of erosion.

The cultivation of irrigated rice in oriental countries reduces erosion to a minimum on nearly all of the land actually used for rice. In China and India, much of the land between the irrigated paddy fields has lost its upper layers of soil to sheet erosion and it is scored by deep gullies. This kind of problem has been alleviated in Japan by intensive reforestation and by other erosion-control measures on land used for unirrigated crops.

Erosion in many European countries has been kept at a low level for several generations through enlightened land-use programs and intensive cultivation and fertilization; but much of the upland soil bordering the Mediterranean Sea has been lost to erosion. Fertile floodplains around the Mediterranean have been badly damaged by deposition of coarse debris washed from cultivated uplands.

Modern soil conservationists recommend using the land in ways that will produce the greatest income consistent with the least loss of soil. They endeavor to protect sloping lands by planting soil-conserving crops, by contour cultivation, by alternation of strips of close-growing crops with clean-cultivated ones, and by using graded terraces and grass-covered waterways to control the rate of flow or runoff of water. Shallow gullies may be filled by plowing, and deep gullies may be controlled by check dams or vegetative cover. However, terraces and dams may be harmful if not well maintained. The large volume of water collected behind terraces and check dams sometimes breaks through, sweeping away large volumes of soil, and scours out new gullies. Ditches that were dug to drain wet lowland soils for farming have provided lower base levels for water flow, and as a consequence gullies have eaten their way back from the ditches high into the adjacent uplands. Many examples of this exist in eastern Nebraska and western Iowa.

The bad effects of wind erosion can be ameliorated on cultivated land by planting strips of close-growing crops in alternation with strips of sod or fallow land arranged at right angles to the prevailing wind. Stubble mulch in semiarid wheat land is highly effective. List-furrowing across the wind is effective in some areas, and shelter belts of trees and shrubs have been helpful to a limited extent. Wind erosion of mulch and peat beds can be greatly reduced by planting wind-breaks at right angles to the prevailing wind.

EROSION (Soil). See **Soil**.

ERRATIC. In geology, an ice-carried boulder or block, sometimes weighing many tons, which because of its lack of similarity to the bedrock or formation on which it rests, and the peculiarity of its position, must have been transported to its present resting place by a glacier or an iceberg. When erratics occur in sufficient quantity to form relatively pronounced topographic features these are called moraines. When erratics of similar or identical lithology show a well-defined lineal distribution from the parent outcrop they are called boulder trains.

ERROR. The word error may be used in two ways: 1. In general, it is a mistake in the colloquial sense, for example, an error in copying, an error of reference, or an error of interpretation. 2. In statistics, the word error is used to denote the difference between an occurring value and its "true" or "expected" value. Specific types of errors and error functions follow:

Error, Approximation. In general, an error due to approximation in numerical calculations as distinct; e.g., an error of observation. More particularly, a rounding error.

Error, Experimental. In general, any error in an experiment whether due to stochastic variation or bias. It is the aim of good experimental design to provide valid measures of the experimental error in the more restricted sense.

Error Band. In estimation or prediction, the estimated or predicted value is bracketed by a range of values (determined by standard errors, confidence-intervals or similar methods) within which the value may be supposed to lie with a certain probability. This is called the error band.

Error Function. The definite integral, also called the Gauss error function,

$$\operatorname{erf}(t) = \frac{2}{\sqrt{\pi}} \int_0^t e^{-y^2} dy$$

When the results of a series of measurements are described about an average by a Gaussian curve, erf(ha) is the probability that the error of a single measurement lies between $\pm a$, where h is the precision index.

Values of the integral, as functions of t, have been tabulated. Sometimes the more general function

$$E_n(t) = n! \int_0^t e^{-y^n} dy$$

is discussed and $E2(t)$ is called the error integral.

Error in Equations. An equation in variables or variates may be inexact, either because the equation is not a complete representation of the situation (as in a demand-supply equation which omits other factors such as income or employment) or because it is disturbed by extraneous sources of variation (as in an autoregression equation). These departures from the relationship expressed by the equation are known as errors in the equation; as distinct from effects such as observational errors in the variables themselves.

Error of Estimation. In general, the difference between an estimated value and the true value. More specifically, in regression analysis where the regression equation is used to estimate the "dependent" from given values of the "independent" variates, the difference between the estimated and the observed value of the dependent variate.

Error of First Kind. If, as the result of a statistical test, a statistical hypothesis is rejected when it ought to be accepted, i.e., when it is true, then an error is committed. This class of error is termed an error of the first kind and is fundamental to the theory of testing statistical hypotheses associated with the names of Neyman and (E.S.) Pearson. The frequency of errors of the first kind can be controlled by an appropriate selection of the regions of acceptance and rejection. That is to say, by choice of appropriate critical regions it is possible to ensure that the probability of committing an error of the first kind is an assignable constant.

Error of Measurement. Much of the routine work in any experimental research in the physical sciences is concerned with the eliminating, minimizing, or compensating for observational errors. By the error of any measurement is meant the result of the individual measurement minus the true value of the quantity measured. It may thus be either positive or negative. Errors of measurement may be broadly classified into two types: instrumental errors and personal errors. An instrumental error is any error in measurement that results from the properties of the instruments used in the measurement. Instrumental errors may be divided into scale errors, which result from improper calibration of the instrument, and reproducibility errors, which result from the failure of the instrument to give the same indication whenever it is subject to the same input signal. While the latter type may be treated as accidental errors, the former may not. A personal error is any error that results from the tendency of an observer to misread an instrument, e.g., to read consistently high or low. Personal errors are not distributed in the same manner as accidental errors, and their magnitudes may be estimated only by the comparison of observations made by different observers. An error of sampling is the discrepancy between the estimate derived from a sample and the true value. The occurrence of errors in this sense is inherent in the incompleteness of sample coverage; they are not "mistakes" in the ordinary sense of the word.

Error of Observation. An error arising from imperfections in the method of observing a quantity, whether due to instrumental or to human factors.

Error of Second Kind. If, as the result of a test, a statistical hypothesis is accepted when it is false, i.e., when it should have been rejected, then an error has been made. This class of error is termed an error of the second kind and, like errors of the first kind it is fundamental to the Neyman-Pearson theory of testing statistical hypotheses. Unlike the error of the first kind, however, it is not, in general, controlled by the simple process of selecting regions of acceptance and rejection. The customary procedure in choosing tests of hypotheses is to fix the magnitude of the first kind of error and, with this restriction, to minimize the second kind of error.

Error Signal. See **Signal (Instrument)**.

Error Variance. The variance of an error component. Thus, if the generating model of a set of data consists of certain systematic components together with a stochastic component, the variance of the latter is in the error variance. The expression can also be understood in a wider sense, as the variance of error in repetitions of an experimental situation, whether the "error" is due to sampling effects or not. It makes for clarity if expressions such as "error variance" are eschewed in favor of "residual variance" but the use of the former type of wording is very widespread.

SIR MAURICE KENDALL, International Statistics, London

ERROR (Common-Mode). See **Common-Mode Voltage**.

ERROR (Computer). In a computer or data-processing system, any incorrect step, process, or result. In addition to the mathematically usage, in the computer field the term is also commonly used to refer to machine malfunctions as machine errors and to human mistakes as human errors. It is frequently helpful to distinguish between these as follows: errors result from approximations used in numerical methods; mistakes result from incorrect programming, coding, data transcription, manual operation, etc.; malfunction result from failures in the operation of machine components such as gates, flip-flops, amplifiers, etc.

ERUPTIVE. This term has the same general geological meaning as effusive. It is sometimes used, in a much more general sense, as synonymous with igneous.

ERYSIPELAS (ST. ANTHONY'S FIRE). Erysipelas is a superficial bacterial skin infection that characteristically extends into the cutaneous lymphatics. Streptococci are the primary cause of erysipelas. Most facial infections are attributed to group A streptococci, with an increasing percentage of lower extremity infections being caused by non–group A streptococci. Streptococcal toxins are thought to contribute to the brisk inflammation that is pathognomonic of this infection. No clear proof has emerged that other bacteria cause typical erysipelas, although they clearly coexist with streptococci at sites of inoculation. Recently, atypical forms reportedly have been caused by *Streptococcus pneumoniae, Klebsiella pneumoniae, Haemophilus influenzae, Yersinia enterocolitica*, and *Moraxella* species, and they should be considered in cases refractory to standard antibiotic therapy.

This disease is most common among the elderly, infants, and children. People with immune deficiency, diabetes, alcoholism, skin ulceration, fungal infections and impaired lymphatic drainage (e.g., after mastectomy, pelvic surgery, bypass grafting) are also at increased risk.

Patients often cannot recall an inciting event, but there may be a history of recent trauma or pharyngitis. Prodromal symptoms, such as malaise, chills, and high fever, often begin before the onset of the skin lesions and usually are present within 48 hours of cutaneous involvement. Pruritus, burning, and tenderness are typical complaints.

Erysipelas begins as a small erythematous patch, which progresses to a fiery-red, indurated, tense, and shiny plaque. Usually the bridge of the nose and cheeks are involved, but other areas of the face and head (ears) may be the site of the lesion. The lesion classically exhibits raised sharply demarcated advancing margins. Local signs of inflammation, such as warmth, edema, and tenderness, are universal. Lymphatic involvement often is manifested by overlying skin streaking and regional lymphadenopathy. More severe infections may exhibit numerous vesicles and bullae along with petechiae and even frank necrosis. With treatment, the lesion often desquamates and can resolve with pigmentary changes that may or may not resolve over time.

Streptococci cause most cases of erysipelas; thus, penicillin has remained first-line therapy. Penicillin administered orally or intramuscularly is sufficient for most cases of classic erysipelas and should be given for 10–20 days. With the use of penicillin therapy, improvement may be achieved within one or two days, but the lesion may not subside for several days. A cephalosporin or macrolide, such as erythromycin or azithromycin, may be used if the patient has an allergy to penicillin. Cephalosporins may cross-react with penicillin first-generation cephalosporins and should not be used in patients with a history of severe penicillin allergy, urticarial reactions, or anaphylaxis.

The most common complications of erysipelas include abscess, gangrene, and thrombophlebitis. Less common complications (<1%) are acute glomerulonephritis, endocarditis, septicemia, and streptococcal toxic shock syndrome. Rare osteoarticular complications involve joints contiguous with the erysipelas plaques and include bursitis, osteitis, arthritis, and tendinitis.

The prognosis for patients with erysipelas is excellent. Complications of the infection usually are not life threatening, and most cases resolve after antibiotic therapy without sequelae. However, local recurrence has been reported in up to 20% of patients with predisposing conditions.

See also **Dermatitis and Dermatosis**.

ERYTHEMA. A reddening of the skin due to capillary dilation. Several forms of erythema can be caused by undue exposure of the human body to weather elements. The most common is sunburn.

ERYTHRITE. A mineral of the composition, $Co_3(AsO_4)_2 \cdot 8H_2O$, isomorphous with annabergite. The color ranges from rose to crimson. The mineral sometimes contains nickel and occurs in monoclinic crystals, in earthy forms (as a weathering product of cobalt ores) in the oxidized portions of the veins, or in globular and reniform masses. The mineral sometimes is referred to as *erythrine*, *cobalt bloom*, and *peachblossom ore*.

ESCARPMENT. A term used by physiographers and structural geologists to denote a line of steep slopes or cliffs.

ESKER. Certain long, often winding, ridges formed of stratified sands and gravels, which occur within the glaciated regions of Europe and North America are called eskers. These pronounced topographic features are frequently several miles in length and because of their peculiar and uniform shape somewhat resemble railway embankments. Eskers represent the deposits of glacial streams, which flowed within and under glaciers. After the retaining ice walls melted away, the stream deposits remained as long winding ridges. Synonyms for esker include os, eschar, serpent kame, and Indian ridge.

ESOPHAGUS. The tube-like passage that connects the lower end of the pharynx (throat) with the stomach. This tube is about 10 inches (25 centimeters) long. It lies in front of the spine as it descends through the chest and passes through the diaphragm just before it enters the stomach. The walls of the esophagus are made up of circular and straight muscle fibers, which allow wave-like contractions to move food downward toward the stomach. The inner surface contains many glands, which secrete mucus for lubrication of the walls. Difficulty of swallowing is a symptom associated with a number of esophageal disorders and is called *dysphagia*. Diagnostic aids sometimes used in identifying esophageal disorders include barium contrast x-rays, esophagoscopy (using a fiberoptic instrument which permits examinations of the tube), and an acid perfusion test, the latter being particularly helpful in the diagnosis of esophagitis. A weak hydrochloric acid solution is administered through a nasoesophageal tube alternately with a saline solution. The presence of pain in response to hydrochloric acid during the test cycle is an excellent indicator of esophagitis and helps the physician differentiate this condition from the similar pain of coronary artery disease.

The principal disorders of the esophagus are as follows. (1) *Chronic peptic esophagitis* is quite common and usually responds well to intermittent antacid therapy. Onset of the condition usually commences an hour or so after meals. There may be regurgitation of small amounts of gastric contents into the mouth. The typical symptom is commonly referred to as *heartburn*. Unresponsive cases may require surgery. This condition is not always associated with a hiatus hernia. (2) *Hiatus hernia* is caused by a portion of the stomach protruding through the hiatus of the diaphragm and into the thoracic cavity. Barium x-ray examination and esophagoscopy are usually required to affirm the disorder. Because the symptoms of chronic peptic esophagitis and hiatus hernia are so similar, a physician may commence with antacid therapy. If the condition persists, cimetidine therapy may be initiated. In the absence of success, surgical repair of the hernia is indicated, along with restoration of the gastroesophageal junction. See also **Hernia**. (3) *Carcinoma of the esophagus*, to date, has proved to be a very high-risk situation. Because of late diagnosis, only about 20% of patients are surgical candidates. The surgery is technically difficult, and may be accompanied by radiation therapy. The five-year survival rate after surgical therapy alone has been estimated at about 10%. Dysphagia is an early symptom of this condition. Other disorders of the esophagus include: (4) lower esophageal ring; (5) diffuse esophageal spasm; (6) achalasia; (7) collagen vascular disease; and (8) esophageal diverticulum.

ESOTROPIA. Esotropia is the most common form of strabismus in infants, a condition that refers to any misalignment of the eyes. In the case, of esotropia one eye deviates inward toward the nose while the other fixates normally. Exotropia is the condition where one eye deviates outward, away from the nose. Strabismus, also called "cross-eye," occurs in about 4% of all children in the United States. It happens equally in males and females and is sometimes hereditary. Esotropia can also affect teenagers and adults, and it is usually related to systemic conditions such as high blood pressure, diabetes, strokes, or brain injuries.

The brain's ability to see three-dimensional objects depends on proper alignment of the eyes. When both eyes are properly aligned and aimed at the same target, the visual portion of the brain fuses the forms into a single image. When one eye turns inward, outward, upward, or downward, two different pictures are sent to the brain. This causes loss of depth *perception and binocular vision*.

Pseudoesotropia (false esotropia) is actually the physical appearance of cross-eye when the eyes are perfectly aligned. Infants and young children often have a wide, flat nose with a fold of skin at the inner eyelid that makes the eyes appear crossed. This appearance usually disappears as the child grows.

Congenital or *infant esotropia* can be present at birth or may develop anytime during the first six months of life. Although it is common for an infant's eyes to be intermittently misaligned, if the condition persists beyond the first few months, it should be checked by a physician. One to 2% of children have congenital esotropia, and the condition usually does not improve with age. Surgical correction is usually recommended between 6 and 14 months of age.

Accommodative esotropia is a common form that occurs in farsighted children, usually 2 years old or older. Young children can often overcome farsightedness by focusing their eyes to adjust to the condition, but the effort required for this focusing causes the eyes to cross. Eyeglasses can reduce the focusing effort and sometimes straighten the eyes. In addition, special eyedrops, ointments, and lenses called prisms may also be effective. Eye exercises can also be helpful, especially in older children. Sometimes bifocals can correct the excessive turning in of the eyes for close work.

Acquired esotropia occurs after infancy. Children who have been farsighted and have not had glasses, or children who were responsive to glasses, but later developed an additional eye-crossing, are the most commonly affected. Children with acquired eye-crossing require prompt evaluation and treatment to correct the deviation and to restore binocular vision.

The causes of some forms of esotropia are not fully understood. There are six muscles that control eye movement, four that move it up and down and two that move it side to side. All these muscles must be coordinated and working properly in order for the brain to see a single image. When one or more of these muscles does not work properly, some form of strabismus may occur. Strabismus is more common in children with disorders that affect the brain such as cerebral palsy, Down syndrome, hydrocephalus, and brain tumors.

Symptoms of esotropia are decreased vision, double vision, and misaligned eyes. Children with esotropia do not use their eyes together and often squint in bright sunlight or tilt their heads in a specific direction to use their eyes together. They may also rub their eyes frequently. Children rarely tell you they are experiencing double vision, although they may close one eye to compensate for the problem. You may also notice signs of faulty depth perception.

When a young child has strabismus, the child's brain may learn to ignore the misaligned eye's image and see only the image from the best-seeing eye. This is called *amblyopia*, or lazy eye, and results in a loss of depth perception. In adults who develop strabismus, double vision sometimes occurs because the brain has already been trained to receive images from both eyes and cannot ignore the image from the turned eye.

Treatment depends on the type of esotropia. Accommodative esotropia can be treated successfully by correcting a refractive error with glasses, patching to force the use of the less-preferred eye, or other forms of therapy. Congenital and acquired esotropia usually require surgery for proper and permanent correction.

The surgeon makes a small incision in the tissue covering the eye in order to reach the eye muscles. Then either tight inner muscles are placed farther back to weaken their pull, or the loose outer muscles are tightened by shortening their length to allow the eye to move outward. The procedure is usually done under general anesthesia. Recovery time is rapid, and normal activities can usually be resumed within a few days. Following surgery, corrective eyeglasses may be needed and, in some cases, further surgery is required later to keep the eyes straight. See also **Amblyopia**; **Extropia**; and **Strabismus (Cross-Eyes)**.

ESSP/GRACE. See **Earth Observing System (EOS)**; and **Earth System Science Pathfinder (ESSP) Program**.

ESTERIFICATION. See **Cellulose Ester Plastics (Organic)**; and **Esters**.

ESTERS. The compound resulting from the reaction of an alcohol with an acid is termed an *ester*. The reaction is termed *esterification* and is accompanied by the yield of H_2O along with the ester. The reaction is highly reversible and hydrolysis will occur in the reverse direction when H_2O remains present. The formation of ethyl nitrate from ethyl alcohol and nitric acid typifies a simple esterification: $C_2H_5OH + HNO_3 \rightleftharpoons C_2H_5NO_3 + H_2O$.

Under normal conditions, esterification occurs slowly and inasmuch as the reaction is fully reversible, an equilibrium is reached which tends to withhold completion of the reaction in either direction.

The esterification reaction can be speeded up by the use of a catalyst. Such a catalyst is hydrogen ion, as from HCl or H_2SO_4. Side reactions may occur, HCl furnishing some organic chloride, and H_2SO_4 causing dehydration of the alcohol. Phosphoric acid generally avoids both these results. Salts that hydrolyze to furnish hydrogen ions are also used, e.g., zinc chloride, aluminum sulfate, ferric chloride, sometimes by the addition of acid to these salts.

The equilibrium point can be displaced to produce more ester by increasing the relative amounts of either the acid or the alcohol as desired.

A complicating factor of considerable significance when recovery of the ester is to be made by distillation is the existence of 2-component (binary) azeotropes of constant boiling points with (1) ester and H_2O and (2) ester and alcohol, and 3-component (ternary) azeotropes with (3) ester and H_2O and alcohol. See also **Azeotropic System**.

Esters are high-tonnage chemicals. Among the more important esters are normal, secondary, and isobutyl acetates, ethyl acetate, normal, secondary, and isoamyl acetates, and methyl acetate. These acetates are used primarily in the lacquer industry. Cellulose nitrate is used in the plastics, lacquer, and explosives industries; cellulose acetate in the plastics and lacquer industries; glyceryl trinitrate in the explosives industry; while cellulose xanthate (viscose) is an important synthetic product for textiles. In the specialized field of plasticizers for the plastics and lacquer industries, numerous synthetic esters are used, for example: butyl stearate, diamyl phthalate, dibutyl oxalate, dibutyl phthalate (also for smokeless powder), dibutyl sebacate, dibutyl tartrate, diethylene glycol monostearate, diethylene glycol distearate, diethyl phthalate, dimethyl phthalate, diphenyl phthalate, glyceryl tripropionate, isobutyl phthalate, tributyl borate, tributyl citrate, tributyl phosphate, tricresyl phosphate, triethylene glycol dihexoate, triethylene glycol dioctoate, triethyl citrate, triethyl phosphate, and triphenyl phosphate. Methyl methacrylate ester is an important plastic. Ethyl silicate is used to cover concrete, brick and stone with a coating of silicic acid to resist water penetration. Diocytl phthalate is used as a plasticizer in cable and wire insulation, and dimethyl phthalate as an insect repellent.

ESTIMATED CEILING. See **Meteorology**.

ESTIMATION (Theory of). Given a sample from a population whose specification involves one or more parameters, it is necessary to form estimates of the parameters. Usually, many different estimates of a given parameter can be derived, and the theory of estimation is concerned with the properties of these different estimates. Together with the estimate itself, it is useful to provide some idea of its precision and this is commonly done by specifying an interval intended to contain the true value of the parameter (see also **Confidence Interval**; and **Fiducial Inference**).

A basic result in the theory of estimation states that, under general conditions, a consistent estimator has a sampling variance in large samples which is not less than a certain lower bound. Statistics whose variance attains this lower bound are said to be efficient. A still more valuable property, which applies for all sample sizes, is that of sufficiency; a sufficient statistic is one that summarizes all the information on the parameter that is contained in the sample. R.A. Fisher has shown that the method of maximum likelihood leads to efficient estimators, and to sufficient estimators where these latter exist. The method of minimum chi-square also leads to efficient estimates in large samples, but in finite samples may fail due to the occurrence of small, expected frequencies.

ESTUARY. An estuary is a partially enclosed body of water formed where freshwater from rivers and streams flows into the ocean, mixing with the salty seawater. Estuaries and the lands surrounding them are places of transition from land to sea, and from fresh to salt water. Although influenced by the tides, estuaries are protected from the full force of ocean waves, winds, and storms by the reefs, barrier islands, or fingers of land, mud, or sand that define an estuary's seaward boundary. Some familiar examples of estuaries include San Francisco Bay, Puget Sound, Chesapeake Bay, Boston Harbor, and Tampa Bay.

Estuaries come in all shapes and sizes, and go by many different names, often known as bays, lagoons, harbors, inlets, or sounds. (Note, not all water bodies by those names are necessarily estuaries. The defining feature of an estuary is the mixing of fresh and salt water, not the name.) Some scientists prefer to describe the environment in terms of the salinity of the water (saline, brackish, or fresh), but saline water is not restricted to marginal marine areas. Such a description does not consider — that it is a region of steep and variable gradient in the environmental conditions. See Fig. 1. If the physiography of estuaries is a sole consideration, they can be defined as "bodies of water bordered by and partly cut off from the ocean by land masses that were originally shaped by nonmarine agencies. They are usually perpendicular to the coast line and most of them occupy the drowned mouths of stream valleys and are, therefore, usually considered as evidence of submergence" (Emery and Stevenson, 1957).

The tidal, sheltered waters of estuaries support unique communities of plants and animals, specially adapted for life at the margin of the sea. Estuarine environments are among the most productive on earth, creating more organic matter each year than comparably-sized areas of forest, grassland, or agricultural land. Many different habitat types are found in and around estuaries, including shallow open waters, freshwater and salt marshes, sandy beaches, mud and sand flats, rocky shores, oyster reefs, mangrove forests, river deltas, tidal pools, sea grass and kelp beds, and wooded swamps.

The productivity and variety of estuarine habitats foster a wonderful abundance and diversity of wildlife. Shore birds, fish, crabs and lobsters, marine mammals, clams and other shellfish, marine worms, sea birds, and reptiles are just some of the animals that make their homes in and around estuaries. These animals are linked to one another and to an assortment of specialized plants and microscopic organisms through complex food webs and other interactions.

Importance of Estuaries

Estuaries are critical for the survival of many species. Tens of thousands of birds, mammals, fish, and other wildlife depend on estuarine habitats as places to live, feed, and reproduce. Estuaries provide ideal spots for migratory birds to rest and refuel during their journeys. And many species of fish and shellfish rely on the sheltered waters of estuaries as protected places to spawn, giving them the nickname "nurseries of the sea". Hundreds of marine organisms, including most commercially valuable fish species, depend on estuaries at some point during their development.

Besides serving as important habitat for wildlife, the wetlands that fringe many estuaries also perform other valuable services. Water draining from the uplands carries sediments, nutrients, and other pollutants. As the water flows through fresh and salt marshes, much of the sediments and pollutants are filtered out. This filtration process creates cleaner and clearer water, which benefits both people and marine life. Wetland plants and soils also

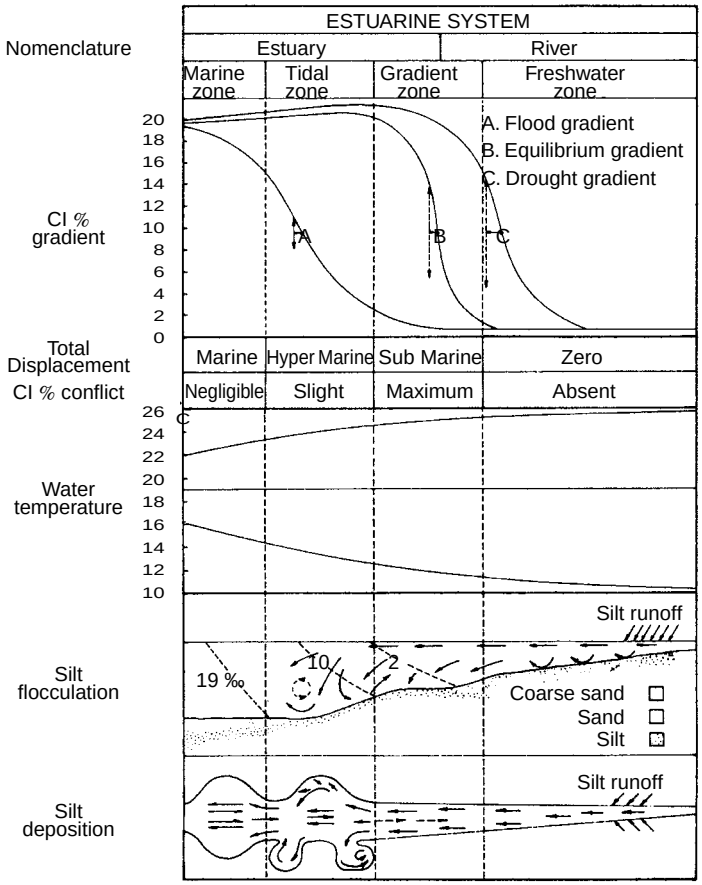

Fig. 1. Some zonal features of a composite Australian estuarine system.

act as a natural buffer between the land and ocean, absorbing floodwaters and dissipating storm surges. This protects upland organisms as well as valuable real estate from storm and flood damage. Salt marsh grasses and other estuarine plants, also help prevent erosion and stabilize the shoreline.

Among the cultural benefits of estuaries are recreation, scientific knowledge, education, and aesthetic values. Boating, fishing, swimming, surfing, and bird watching are just a few of the numerous recreational activities people enjoy in estuaries. Estuaries are often the cultural centers of coastal communities, serving as the focal points for local commerce, recreation, celebrations, customs, and traditions. As transition zones between land and water, estuaries are invaluable laboratories for scientists and students, providing countless lessons in biology, geology, chemistry, physics, history, and social issues. Estuaries also provide a great deal of aesthetic enjoyment for the people who live, work, or recreate in and around them.

Finally, the tangible and direct economic benefits of estuaries should not be overlooked. Tourism, fisheries, and other commercial activities thrive on the wealth of natural resources estuaries supply. The protected coastal waters of estuaries also support important public infrastructure, serving as harbors and ports vital for shipping, transportation, and industry. Some attempts have been made to measure certain aspects of the economic activity that depends on America's estuaries and other coastal waters:

Classification of Estuaries. There is no system that is universally used to classify estuaries. A broad classification separates normal (or positive) estuaries, in which freshwater inflow exceeds evaporation, from inverse (hypersaline) estuaries in which evaporation exceeds freshwater inflow. Neutral estuaries are those in which neither evaporation nor river discharge dominate.

Estuaries along most coastlines have been formed partly by the subsidence of the land mass and partly by the rise in sea level. These embayments are usually elongate indentures of the coastline with rivers flowing in from the landward ends. Deep estuaries are known as *rias*. In eastern North America most estuaries are shallow with irregular, or dendritic, shore lines and are normal estuaries.

Along the Gulf Coast of the United States, marine processes have built a series of barrier islands parallel to the coastline. Most of the islands extend across the mouths of estuaries, forming a lagoon and decreasing the width of the estuarine entrance to the open sea.

The exchange of water, in such cases, between the estuary and the open sea is modified by the intervening lagoon in which evaporation may exceed freshwater inflow. The waters in the estuary, then, have salinities higher than normal as a result of the exchange with the lagoon water.

Water Characteristics and Circulation. The important feature in an estuary is the intermixing of seawater with the freshwater from land drainage. This interaction usually produces a variation, both horizontal and vertical, in the salinity of estuarine waters. In normal estuaries, salinities range from nearly zero at the river's mouth, to approximately 30% at the seaward extremity. In addition, there is generally an increase in salinity with depth.

An inverse estuary also has greater salinities at depth, but the highest salinities are at the head of the embayment rather than at the mouth. There may be a difference of several parts per thousand between the salinity at the head and that of normal seawater. See Fig. 2.

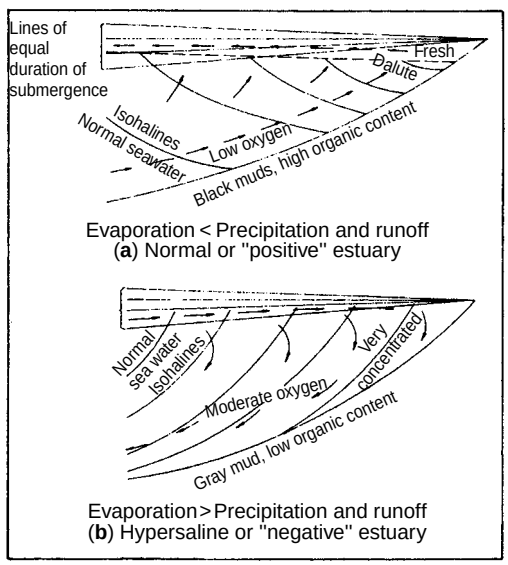

Fig. 2. Schematic sections of the two basic types of estuaries.

Temperature. The water in estuaries, and especially that overlying the tidal flats, is relatively thin, so it follows the variations in temperature of the atmosphere more closely than does the water of the open sea. The water is much colder in winter and warmer in summer than is the sea. The diurnal variation is also greater than in the sea.

There are pronounced variations in water temperature with depth. During the winter, the water is cold and nearly isothermal at all depths. In some instances, in response to cold weather, the surface water may become a degree or so colder than the deeper water. During the summer, solar radiation and minor wind mixing produce a high temperature at the surface with less change at depth. The difference between surface and bottom temperatures may also be influenced by warm or cold river water flowing over the dense seawater.

Where evaporation exceeds river inflow, the summer surface water may become so saline as to sink to the floor of the estuary and flow out of the entrance beneath the incoming seawater. The temperature of the deep water may then be higher than that at the surface.

Circulation. Water movements in estuaries result mainly from the interaction of tides, river flow, and wind. The tides and river flow are usually the dominant factors. In Gulf Coast estuaries, where the tide range is small and river discharge is at times negligible, wind-induced currents are most important.

Stable estuaries. In normal estuaries, the distribution of temperature and salinity, and the circulation pattern, are controlled almost exclusively by the tide range and the river inflow. Tidal currents tend to produce turbulent mixing of the river water and the seawater. However, the low-density

freshwater above the seawater results in a stable vertical stratification which resists mixing. As a consequence, the relative magnitudes of the river discharge and the tidal flow are significant in controlling the physical structure of the water in the estuary.

Where the river flow is large in relation to the tidal exchange, the seawater enters the estuary as a salt-water "wedge" along the bottom. However, there is frictional drag between the overlying freshwater, the salt-water wedge, and the bottom. The relative velocities of the seaward-flowing freshwater and the intruding salt-water wedge control the magnitude of the friction factor. Thus, the actual position of the wedge is closely dependent on the volume of the river flow. When the volume of river discharge is great, the wedge extends only a short distance into the estuary and, of course, vice versa.

The salinity of the salt-water wedge remains similar to that of the open sea because there is only minor mixing with the seaward-flowing freshwater. However, at the interface between the two types of water, waves form and sometimes intrude into the surface water. Thus, the salt content in the upper layers increases slightly as the water moves seaward. Even so, throughout the estuary, a sharp salinity gradient exists between the two water layers.

The loss of salt water from the wedge to the upper layer is compensated by a flow of water from the sea (Fig. 2). The exchange from below takes place all along the upper interface of the wedge. As a result, there is a flow directed upstream at all positions within the wedge. The landward-moving water in the salt wedge is minor, however, and of the two, the seaward flow of surface water is far greater.

Partly mixed estuaries. Where tidal movements are great as compared to the volume of river discharge, mixing between the seawater and freshwater is sufficient to destroy sharp interfaces. The salt wedge, in such cases, does not exist as an identifiable feature, but a transition layer of definitely increasing salinity does occur. In such an estuary, however, the salinity in both the upper and lower layers decreases toward the head of the estuary.

The chief cause of currents in estuaries in which the waters are partly mixed is the tide. As in the stratified estuary, there is a net water movement superimposed on the tidal currents — a net seaward flow at the surface and a net flow toward the head in the deeper layers. These water motions are not as well defined as in a stratified estuary, and there is no sharp current interface. The flow from the deeper layers toward the surface decreases toward the head of the embayment. The volume rate of seaward flow increases, therefore, toward the mouth.

Mixed estuaries. In wholly mixed estuaries, the movements induced by the tide are far greater than those produced by the river inflow. The waters are completely mixed and are isohaline from the surface to the bottom. At all depths, the salinity decreases from the mouth to the head.

In such estuaries, the outward flowing water is deflected to the right, in the Northern Hemisphere, because of earth rotation. Thus, in wide estuaries, the salinity is less on the right side (looking toward the estuarine mouth) than on the left. A net seaward flow exists along the right side and a net landward flow on the left. Water also moves laterally across the estuary from the left to the right side resulting in horizontal mixing.

In narrow, well-mixed estuaries, mixing induced by tidal action may be great enough to eliminate any lateral salinity gradient. There is a net seaward flow in all waters and the only difference in salinity is the normal decrease toward the head.

Estuaries bordered by lagoons. Along coastal regions where barrier islands extend across the mouths of estuaries, the water bodies are usually so shallow that mixing by winds is sufficient to produce homogeneous water. Tidal currents are only significant through the inlets between the barrier islands. The total volume of water that flows in and out is relatively small. As a consequence, the rise and fall of the tide and tidal currents are minor within the estuary, and the most significant currents are from wind action.

There is, necessarily, a net flow of water out of these shallow estuaries sufficient to remove the water added by freshwater discharge. The large cross-sectional area of the estuary and the dampening effect of the coastal lagoon reduce the flow so that it is normally not directly measurable. The net motion may be completely modified by wind action to the extent that high water and constant, net inflow may occur during times when prevailing winds blow up the estuary. Strong winds blowing from the land reverse this effect and result in extremely low water levels in the estuary and the extrusion of estuarine waters many miles to sea.

Seiches in estuaries. In some of the larger estuaries, the periodic flooding by the tides is supplemental by seiches, long stationary waves. The simplest seiche is one whose node is at the mouth of the estuary and the antinode near the head. The period of the seiche is controlled by the length and depth of the body of water; where its natural period nearly coincides with that of the tide, as at the Bay of Fundy, a great fluctuation in sea level occurs (about 15 meters). In most estuaries, the seiche is only a few centimeters and is obscured by the much greater tidal amplitude.

Waves. Wind waves are small in estuaries because of the short fetch and the shallow water. They usually cause little erosion although when the tide is high, waves may stir up the muddy sediment on tidal flats. Waves may transport some sand and, because the largest waves come across the widest part of the estuary, they form sand spits pointing upstream in tidal channels.

A tidal bore (a wave of translation) is common in narrow estuaries and tidal channels. As a result of the shape of the entrance and bottom friction, the flooding tide is held back for a time until the water finally rushes up the channel as a steep wall of water. Bores may be from a few centimeters to several meters in height and move at velocities as great as 10 knots. The character of a tidal bore is determined, in part, by the river discharge which must be sufficient to hold back the tide for a period of time.

Estuarine sediments. The inorganic sediments of estuaries are derived from inflowing rivers bordering sea cliffs, the sea floor outside the estuary, and the reworked deposits of tidal flats and marshes along the shores. Regardless of the source, much reworking of sediment occurs within estuaries. Erosion, too, is evident from the migration of tidal channels and the muddy color of the water when no river inflow is taking place. Some estuaries have entrances narrow enough so that tidal currents scour the bottom locally, leaving rocky or gravelly bottoms. The prevailing condition, however, must be one of deposition, and the average rate of deposition is greater than that of the open sea.

ETESIANS. See **Winds and Air Movement**.

ETHANE. [CAS: 74-84-0] C_2H_6, formula weight 30.07, colorless, odorless gas, mp $-172\,^{\circ}C$, bp $88.6\,^{\circ}C$, sp gr 1.05 (air = 1.0), practically insoluble in H_2O, moderately soluble in alcohol. The compound burns when ignited in air with a pale faintly luminous flame; forms an explosive mixture with air over a moderate range. With excess air, products of combustion are CO_2 and H_2O. Ethane is among the chemically less reactive organic substances. However, ethane reacts with chlorine and bromine to form substitution compounds. Ethane occurs, usually in small amounts, in natural gas. The fuel value of ethane is high, 1,730 Btu per cubic foot. Ethane may be prepared by reaction of magnesium ethyl iodide in anhydrous ether (Grignard's reagent) with H_2O or alcohols. Ethyl iodide, ethyl bromide, or ethyl chloride, are preferably made by reaction with ethyl alcohol and the appropriate phosphorus halide. Important ethane derivatives, by successive oxidation, are ethyl alcohol, acetaldehyde, and acetic acid.

ETHANOLAMINES. There are three ethanolamines, all hydroxyamines, and all high-tonnage industrial chemicals. Production is about 300 mil pounds annually.

Monoethanolamine, $NH_2CH_2CH_2OH$, industrial symbol (MEA) Formula weight 61.08, mp 10.5 °C, bp 171 °C, sp gr 1.018
Diethanolamine, $NH(CH_2CH_2OH)_2$, industrial symbol (DEA) Formula weight 105.14, mp 28.0 °C, bp 270 °C, sp gr 1.019
Triethanolamine, $N(CH_2CH_2OH)_3$, industrial symbol (TEA) Formula weight 149.19, mp 21.2 °C, bp 360 °C, sp gr 1.126

Mono- and triethanolamine are miscible with H_2O or alcohol in all proportions and are only slightly soluble in ether. Dietanolamine will dissolve in H_2O up to 96.4% at 20 °C, is very soluble in alcohol, and only slightly soluble in ether.

Wurtz first reported the ethanolamines in 1860, but they were not used commercially on any scale until the late 1920s. All of the compounds are clear, viscous liquids at standard conditions and white crystalline solids when frozen. They have a relatively low toxicity. Industrially, the compounds are important (1) because they form numerous derivatives, notably with fatty acids, soaps, esters, amides, and esteramides; and (2) for their exceptional ability for scrubbing acidic compounds out of gases. Monoethanolamine, for example, will effectively remove H_2S from hydrocarbon gases. The compounds also remove CO_2 from process streams and, where desired, the CO_2 may easily be recovered by heating the absorptive solutions. The soaps of the ethanolamines are extensively used in textile treating agents, in shampoos, and emulsifiers. The fatty acid amides of diethanolamine are applied as builders in heavy-duty detergents, particularly those in which alkylaryl sulfonates are the surfactant ingredients. The use of triethanolamine in photographic developing baths promotes fine grain structure in the film when developed. Ethanolamine also is used as a humectant and plasticizing agent for textiles, glues, and leather coatings; and as a softening agent for numerous materials. Morpholine is an important derivative.

In early processes, the ethanolamines were prepared by reacting ethylene chlorohydrin $ClCH_2 \cdot CH_2OH$ with NH_3. Current processes react ethylene oxide $\langle(CH_2)_2\rangle O$ with NH_3, usually in aqueous solution. The ratio of mono-, di-, and triethanolamines varies in accordance with the amount of NH_3 present. This is controlled by the quantities of MEA and DEA recycled. Higher NH_3-ethylene oxide ratios favor high DEA and TEA yields, whereas lower ratios are used where maximum production of MEA is desired. The reaction is noncatalytic. The pressure is moderate, just sufficient to prevent vaporization of components in the reactor. The bulk of the H_2O produced in the reaction is removed by subsequent evaporation. The dehydrated ethanolamines then proceed to a further drying column, after which they are separated in a series of fractionating columns, not difficult because of the comparatively wide separation of their boiling points.

ETHANOL. See **Ethyl Alcohol**.

***e* (The Number).** A transcendental number, used as the base of the system of natural or Napierian logarithms. It is defined by

$$e = \lim_{n\to\infty} (1 + 1/n)^n$$

or by

$$e = \lim_{x\to 0} (1 + x)^{1/x}$$

It is represented by the infinite series

$$e = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \frac{1}{4!} + \cdots + \frac{1}{n!} + \cdots$$

and it equals 2.71828, approximately. In this book, the number *e* is written in italic form, except in equations involving electrical quantities, where the Roman e is used to avoid confusion.

See also **Logarithm**.

ETHERNET. See **Transmission Control Protocol (TCP)/Internet Protocol (IP) Suite**.

ETHERS. Ethers are compounds of the general formula Ar−O−Ar′, Ar−O−R , and R−O−R′ where Ar is an aryl group and R is an alkyl group. If the two R or Ar groups are identical, the compound is a symmetrical ether. Examples of symmetrical ethers are (di)methyl ether, CH_3OCH_3, and (di)phenyl ether, $C_6H_5OC_6H_5$; examples of unsymmetrical ethers are methyl ethyl ether, $CH_3OCH_2CH_3$, and methyl *tert*-butyl ether, $CH_3OC(CH_3)_3$. Cyclic ethers are variously designated. Three-membered ring cyclic ethers are olefin oxides, eg, ethylene oxide **(1)**, 1,2-propylene oxide, and 1,2-butylene oxide. This ether group is also known as an epoxy group or oxirane. When the ring containing the ether is larger, the ethers are usually classified as oxygen heterocyclics such as tetrahydrofuran (THF)**(2)**, or *p*-dioxane **(3)**.

(1) (2) (3)

Simple ethers derive their name from the two groups attached to the oxygen followed by the word ether, eg, diethyl ether, $CH_3CH_2OCH_2CH_3$. For symmetrical ethers the "di" prefix is often omitted. If one group has no simple name, the compound may be named as an alkoxy derivative, eg, 2-ethoxyethanol, $CH_3CH_2OCH_2CH_2OH$.

Diethyl ether [CAS: 60-29-7] commonly called simply *ether*, is one of the more important members of the ether family. It is a colorless, very volatile, highly flammable liquid with a sweet, pungent odor and burning taste. As a commercial product it is available in several grades; it is used in chemical manufacture, as a solvent, extractant, or reaction medium, and as a general anesthetic.

Methyl Tertiary Butyl Ether (MTBE) [CAS: 1634-04-4] was first commercially produced in Italy in 1973 for use as an octane enhancer in gasoline. U.S. production of MTBE started in 1979 after Atlantic Richfield Co. (ARCO) was granted a waiver by the U.S. Environmental Protection Agency (EPA) that allowed MTBE to be blended up to 7 vol % in U.S. unleaded gasoline. The use of other aliphatic ethers was allowed when the U.S. EPA issued its "substantially similar" definition for unleaded gasoline specifications in 1981. Under this definition, any aliphatic ether or ether mixture could be blended in unleaded gasoline as long as the total oxygen contribution from the ethers does not exceed 2.0% oxygen by weight in the gasoline. This allowed MTBE to be blended up to approximately 11 vol % in gasoline.

MTBE production grew during the 1980s as lead-based octane enhancers were being phased out of gasoline. In August 1988, U.S. EPA granted a waiver requested by Sun Refining and Marketing Co. that allowed the use of MTBE up to 15 vol %, which is approximately equal to 2.7 wt % oxygen in gasoline. This oxygen limit was extended to all aliphatic ethers in gasoline in 1990 when the U.S. EPA raised the oxygen in the "substantially similar" definition to 2.7 wt % oxygen.

In November 1990, the U.S. government again revised the Clean Air Act (CAA). One of the new requirements was for gasolines sold in ambient air quality nonattainment areas of the United States to contain a minimum amount of oxygen. For the 39 metropolitan areas that exceed the federal standard for carbon monoxide, the gasoline would have to contain at least 2.7 wt % oxygen for at least four winter months beginning November 1992. This represents nearly 30% of the U.S. gasoline market.

Except for the special case of the epoxides, THF represents the largest use of a heterocyclic ether. Its consumption is also much larger than that of ethyl ether. Unlike the dialkyl ethers, THF is totally miscible in water at ambient conditions. Its cyclic structure also allows it to be more reactive than the dialkyl ethers. More than half of the THF produced is used as an intermediate in making other chemicals or elastomers.

Physical Properties

In general, ethers are neutral, pleasant-smelling compounds that have little or no solubility in water, but are easily soluble in organic liquids. Their boiling points approximate those of hydrocarbons having comparable molecular weights and geometries.

Chemical Properties

Most ethers, particularly dialkyl ethers, are comparatively unreactive compounds because the carbon-oxygen bond is not readily cleaved. For

this reason, ethers are frequently employed as inert solvents in organic synthesis. However, within the ether family, the cyclic ethers are more reactive, the most reactive being the olefin oxides or epoxides. Epoxides are generally used as intermediates for producing other small molecules or polymers. See also **Epoxy Resins**; and **Polyethers**. Ethers do react with exceptionally powerful basic reagents, particularly certain alkali metal alkyls, to give cleavage products. Ethers react with less powerful bases to give the same cleavage products, but only under the forcing conditions of high temperature and pressure.

$$CH_3Na + CH_3CH_2OCH_2CH_3 \rightarrow CH_4 + CH_2 = CH_2 + CH_3CH_2ONa$$

The ether linkage can also be cleaved by strong acids, generally at high temperatures:

$$(CH_3)_2CHOCH(CH_3)_2 + 2HBr \overset{140\,^\circ C}{\rightarrow} 2(CH_3)2CHBr + H_2O$$

$$C_6H_5OCH_3 + HI \overset{130\,^\circ C}{\rightarrow} C_6H_5OH + CH_3I$$

Other acids that have been used for this cleavage are phosphoric acid, pyridine hydrochloride, boron tribromide, trifluoroacetic acid, and nitric acid. Acid cleavage of aryl alkyl ethers always gives phenol because the aromatic carbon–oxygen bond is much stronger than the aliphatic carbon–oxygen bond. Unsymmetrical aliphatic ethers usually yield a mixture of alkyl halides and alcohols when cleaved by halogen containing acids.

Most ethers are potentially hazardous chemicals because, in the presence of atmospheric oxygen, a radical-chain process can occur, resulting in the formation of peroxides that are unstable, explosion-prone compounds.

The nature of the initiation step, which may occur in a variety of ways, is not known in all cases. Commonly used ethers such as ethyl ether, isopropyl ether, tetrahydrofuran, and p-dioxane are particularly prone to form explosive peroxides on prolonged storage and exposure to air and light, and should contain antioxidants to prevent their build-up. One of the exceptions to the peroxide forming tendency of ethers is methyl *tert*-alkyl ethers such as methyl *tert*-butyl ether (MTBE) and *tert*-amyl methyl ether [CAS: 994-05-8] (TAME). Both have shown little tendency if any to form peroxides. See also **Antioxidants**; and **Peroxides and Peroxide Compounds (Organic)**.

Ethers are weakly basic and are converted to unstable oxonium salts by strong acids such as sulfuric acid, perchloric acid, and hydrobromic acid; relatively stable complexes are formed between ethers and Lewis acids such as boron trifluoride, aluminum chloride, and Grignard reagents:

$$CH_3OCH_3 + CH_3BF_4 \rightarrow (CH_3)_3O^+BF_4^-$$

Like other aromatic compounds, aromatic ethers can undergo substitution in the aromatic ring with electrophilic reagents, eg, nitration, halogenation, and sulfonation. They also undergo Friedel-Crafts) alkylation and acylation.

Allyl phenyl ethers rearrange cleanly at high temperatures, producing *o*-allyl phenols or *p*-allylphenols if both ortho positions are blocked. This reaction is called the Claisen rearrangement.

In addition to MTBE, two other ethers commonly used as fuel additives are tert-amyl methyl ether (TAME) and ethyl tert-butyl ether [CAS: 637-92-3] (ETBE). See also **Gasoline and Other Motor Fuels**.

Manufacturing of Commercially Important Ethers

Ethyl Ether. Much of the diethyl ether manufactured is obtained as a by-product when ethanol is produced by the vapor-phase hydration of ethylene over a supported phosphoric acid catalyst. Such a process has the flexibility to adjust to some extent the relative amounts of ethanol and diethyl ether produced in order to meet existing market demands. Diethyl ether can be prepared directly to greater than 95% yield by the vapor-phase dehydration of ethanol in a fixed-bed reactor using an alumina catalyst. See also **Ethyl Alcohol**; and **Ethylene**.

Methyl tert-Butyl Ether. MTBE is easily made by the selective reaction of isobutylene and methanol over an acidic ion-exchange resin catalyst, in the liquid phase and at temperatures below 100 °C. To be economically competitive, MTBE's use as an octane enhancer in gasoline has been dependent on low cost isobutylene. There are a number of possible isobutylene sources for making MTBE. See also **Butylenes**. During the 1980s, much of the MTBE was made with isobutylene contained in mixed butanes/butylenes process streams that was produced from petrochemical olefin plants or refinery fluid catalytic crackers. MTBE plant sizes from these feedstock sources are limited by the amount of by-product isobutylene produced in these operations, and are usually in the range of one to six thousand barrels per day (40 to 250 t/yr). Larger amounts of isobutylene for MTBE can be made from butanes by first isomerizing the normal butanes to isobutane, and then dehydrogenating to isobutylene. This is a much more capital intensive process, and therefore the plant sizes in the United States are usually at least 500,000 t/yr to be economically competitive. Even at this size, it is still a relatively higher cost source of MTBE than that made from by-product isobutylene in ethylene plants or refineries.

Tetrahydrofuran. Almost all the THF in the United States is currently produced by the acid-catalyzed dehydration of 1,4-butanediol. Du Pont claimed a new low cost process for producing THF from *n*-butane. This process transport-bed oxidizes n-butane to crude maleic anhydride, then follows with a hydrogen reduction of aqueous maleic acid to THF.

Other Ethers.

n-Butyl Ether. *n*-Butyl ether is prepared by dehydration of *n*-butyl alcohol by sulfuric acid or by catalytic dehydration over ferric chloride, copper sulfate, silica, or alumina at high temperatures.

Isopropyl Ether. Isopropyl ether is manufactured by the dehydration of isopropyl alcohol with sulfuric acid. It is obtained in large quantities as a by-product in the manufacture of isopropyl alcohol from propylene by the sulfuric acid process, very similar to the production of ethyl ether from ethylene. Isopropyl ether is of moderate importance as an industrial solvent, since its boiling point lies between that of ethyl ether and acetone.

Tertiary-Amyl Methyl Ether. Like MTBE, TAME is produced by the simple reaction of methanol and isoamylenes (2-methyl-1-butene and 2-methyl-2-butene).

Ethyl tertiary-Butyl Ether. Similar to methanol in the MTBE reaction, ethanol can react with isobutylene to produce ETBE. Which alcohol is used to make the ether is highly dependent on the relative cost of the alcohols. To make ethanol more economically competitive with methanol, the federal tax credit for biomass-based ethanol used in fuel also applies to ethanol used to make ETBE in the United States.

Vinyl Ether. Vinyl ether is manufactured by the pyrolytic dehydrochlorination of 1,1′-dichloroethyl ether.

2-Methoxyphenol. This ether is prepared by methylating 1,2-dihydroxybenzene.

Butylated Hydroxyanisole. 2- and 3-*tert*-Butyl-4-methoxyphenol (butylated hydroxyanisole (BHA)) is prepared from 4-methoxyphenol and *tert*-butyl alcohol over silica or alumina at 150 °C or from hydroquinone and *tert*-butyl alcohol or isobutene, using an acid catalyst and then methylating.

Specifications

Ethyl ether is commercially available in the following grades: USP anesthesia, absolute (ACS) industrial, solvent (conc), and synthetic. Specifications vary, depending on the consumer and use. In many instances, the ether has to meet a specific test written into the specification, eg, it may be important that the ether is completely anhydrous or free from alcohol and aldehyde.

The technical concentrated ether contains very small amounts of alcolhol, water, aldehydes, peroxides, and other impurities. The more refined grades, such as anesthetic ether, are obtained from technical ether by redistillation and dehydration followed by alkali or charcoal treatment.

Ethyl ether is classified by the ICC as a flammable liquid. As such, it must be packed in ICC specification containers when shipped by rail, water, or highway; all ICC regulations regarding loading, handling, and labeling must be followed. Each container of ethyl ether must carry an identifying label or stencil. Tank cars and boxcars, either carload or less than carload, must bear the ICC dangerous placard. Each drum or each box with inside containers must bear the ICC red label for flammable liquids.

For fuel-grade MTBE, the typical specification of merchant product is 95 wt % minimum purity in the United States and 98% minimum in Europe. The maximums for impurities are usually 0.5 wt % for methanol,

and 0.15 wt % for water. To maintain quality, fuel-grade MTBE is normally stored in fixed-roof tanks, to keep rain water out, with internal floaters, to minimize vapor losses.

Besides its use in gasoline, a high purity refined grade (99.9% min) of MTBE is produced for other industrial uses. The general industry specifications are a minimum purity of 99.9 wt %. Maximum impurities are 300 ppm water and 150 ppm of the hydroperoxide of THF. Like most ethers, it is prone to forming peroxides on storage, and therefore is usually sold containing an antioxidant such as BHT.

Analytical Methods

Most of the analytical and testing methods used for ethyl ether are conventional laboratory methods. Ethyl ether that is to be used for anesthetic purposes or in processes that involve heating or distillation must be peroxide-free, and should pass the USP standard test with potassium iodide. This test detects approximately 0.001% peroxide as hydrogen peroxide.

Health and Safety Factors

Although ethers are not particularly hazardous, their use involves risks of fire, toxic effects, and several unexpected reactions.

Since almost all ethers burn in air, an assessment of their potential hazards depends on flash points and ignition temperatures. The flash point of a liquid is the lowest temperature at which vapors are given off in sufficient quantities for the vapor–air mixture above the surface of the liquid to propagate a flame away from the source of ignition. In other words, an explosive vapor–air mixture can form whenever a liquid is used or stored in an open container at a temperature above its flash point. Table 2 includes the flash points of several common ethers.

The ignition temperature is the minimum temperature required to initiate or cause self-sustained combustion. Table 2 also lists ignition temperatures of several common ethers. Attention is directed to the particularly low ignition temperature of ethyl ether, especially with reference to some common ignition sources such as a lighted cigarette (732 °C) or a pressurized (0.7 MPa or 100 psi) steam line (180 °C).

If an ethyl ether fire occurs, carbon dioxide, carbon tetrachloride, and dry chemical fire extinguishers meeting National Fire Prevention Association Code 1 and 2 requirements may be used successfully (*Chemical Safety Data Sheet SD-29*, Manufacturing Chemist Association, Washington, D.C., 1972.). Water may also be effectively applied. Hose streams played into open tanks of burning ethyl ether serve only to scatter the liquid and spread the fire. However, ether fires may be extinguished by a high pressure water spray that cools the burning surface and smothers the fire. Automatic sprinklers and deluge systems are also effective.

The effect of ethers owing to ingestion, skin contact, or inhalation may range from drowsiness and lack of coordination to serious injury or death. Ethers are reported to have a low order of toxicity when ingested, although 30–60 mL may be fatal when swallowed [Gleason, et. al.], and a case of fatal poisoning owing to ingestion of a large quantity of 2-methoxyethanol has been recorded.

Prolonged or repeated contacts of ethers with skin cause tissue defatting and dehydration leading to dermatitis. Some compounds penetrate the skin in harmful amounts. Inhalation is the most common means by which ethers enter the body. The effects of various ethers may include narcosis, irritation of the nose, throat, and mucous membranes, and chronic or acute poisoning. In general, ethers are central nervous system depressants, eg, ethyl ether and vinyl ether are used as general anesthetics.

The toxicity of ethyl ether is low and its greatest hazards in industry are fire and explosion. The vapor is absorbed almost instantly from the lungs and very promptly from the intestinal tract. It undergoes no chemical change in the body. Prevention and control of health hazards associated with the handling of ethyl ether depend primarily on prevention of exposure to toxic atmospheric concentrations and scrupulous precautions to prevent explosion and fire.

ETHOLOGY. The study of animal behavior, particularly under natural conditions, ethology embraces the concepts of altruism and other aspects of sociobiology.

ETHYL ALCOHOL. [CAS: 64-17-5] C_2H_5OH, formula weight 46.07, is a colorless liquid with mild characteristic odor, mp −114.1 °C, bp 78.32 °C, sp gr 0.789. Also known as *ethanol*, the compound is miscible in all proportions with H_2O or ether. When ignited, ethyl alcohol burns in air with a pale blue, transparent flame, producing H_2O and CO_2. The vapor forms an explosive mixture with air and it is used in some internal combustion engines under compression as a fuel. See also **Fuel**. Such mixtures are frequently referred to as *gasohol*.

Anhydrous ethyl alcohol is made from the constant boiling mixture with H_2O (95.6% ethyl alcohol by weight)—(1) by heating with a substance such as calcium oxide, which reacts with H_2O and not with alcohol, and then distilling, or (2) by distilling with a volatile liquid, such as benzene (bp 79.6 °C), which forms a constant low-boiling mixture with H_2O and alcohol (bp 64.9 °C), so that H_2O is removed from the main portion of the alcohol; after which alcohol plus benzene distills over (bp 78.5 °C). Anhydrous ethyl alcohol is required for certain purposes as a solvent and reagent and fuel applications.

Commercially, ethyl alcohol is marketed by the proof gallon, 200 proof on the scale representing pure alcohol (100%). When the term *alcohol* alone is used, it refers to a liquid that ranges from 188 to 192 proof (94% to 96% ethyl alcohol). When the terms *grain alcohol*, *high-purity* alcohol, or *pure ethyl* alcohol are used, these usually refer to a liquid that is 190 proof. In most countries, beverage alcohol is highly taxed and to make the product available for nonbeverage purposes, denaturants will be added. Denaturants include methyl alcohol, pyridine, benzene, kerosene, pine oil, mixtures of primary and secondary aliphatic higher alcohols, and hydrogenated organic compounds. Thousands of nonbeverage industrial and commercial products, notably food extracts, toiletries, pharmaceuticals, solvents, and cleaning products, contain denatured ethyl alcohol.

Worldwide, ethyl alcohol is the basis for a huge alcoholic beverage industry, offering a wide range of products wherein the alcoholic content varies from a few to over 50% (100 proof). Industrially, ethyl alcohol is very important high-tonnage raw and intermediate material for numerous processes, and is used extensively in solvents, antiseptics, antifreeze compounds, and fuels.

Production

Natural fermentation is the oldest process for making ethyl alcohol and still constitutes the principal means for creating the alcoholic content of beverages. Except in connection with other alcohol-containing products, industrial producers of ethyl alcohol use processes other than fermentation. For fermentation, almost any agricultural raw material with a carbohydrate content in the form of sugars or starches that are easily converted to sugars can be used. Once the raw materials are in the form of sugars, yeast enzymes are added to commence natural fermentation. Traditionally, in the United States, industrial alcohol prepared by fermentation has used blackstrap molasses, which contains up to 50% sugars and can be easily fermented. The starting mash is prepared by diluting the molasses with H_2O to bring the sugar content down to about 15% (weight). The mash is slightly acidified, after which invertase (enzyme

to convert sucrose) and zymase (enzyme to convert glucose and fructose) are added. The products are ethyl alcohol and CO_2. Yeast activity is sustained by the addition of nutrients. With careful control of temperature and acidity, the fermentation process can be completed in about two days. The resulting mash (beer) usually contains about 12% ethyl alcohol which is recovered from the beer by distillation. See also **Fermentation**.

In modern industrial ethyl alcohol plants, the compound is produced in two principal ways: (1) by *direct hydration of ethylene*, or (2) by *indirect hydration of ethylene*. In the direct hydration process, H_2O is added to ethylene in the vapor phase in the presence of a catalyst: $CH_2 : CH_2 + H_2O \rightleftarrows CH_3CH_2OH$. A supported acid catalyst usually is used. Important factors affecting the conversion include temperature, pressure, the H_2O/CH_2:CH_2 ratio, and the purity of the ethylene. Further, some byproducts are formed by other reactions taking place, a primary side reaction being the dehydration of ethyl alcohol into diethyl ether: $2C_2H_5OH \rightleftarrows (C_2H_5)_2O + H_2O$. To overcome these problems, a large recycle volume of unconverted ethylene usually is required. The process usually consists of a reaction section in which crude ethyl alcohol is formed, a purification section with a product of 95% (volume) ethyl alcohol, and a dehydration section which produces high-purity ethyl alcohol free of H_2O. For many industrial uses, the 95%-purity product from the purification section suffices.

In the indirect hydration process, ethylene first is absorbed in concentrated H_2SO_4 to form mono- and diethyl sulfates: $CH_2 : CH_2 + H_2SO_4 \rightarrow CH_3CH_2OSO_3H$; and

$$2CH_2 : CH_2 + H_2SO_4 \longrightarrow (CH_3CH_2)_2SO_4.$$

The ethyl sulfates then are hydrolyzed to ethyl alcohol: $CH_3CH_2OSO_3H + H_2O \rightarrow CH_3CH_2OH + H_2SO_4$; and

$$(CH_3CH_2)_2SO_4 + 2H_2O \longrightarrow 2CH_3CH_2OH + H_2SO_4.$$

Remaining steps in the process include recovery and purification of the crude ethyl alcohol and reconcentration of the dilute H_2SO_4. The crude ethyl alcohol is steam-stripped from the dilute acid solution, followed by distillation for purification.

Azeotropes. The physical properties of ethyl alcohol are influenced by the hydroxyl group that imparts hydrogen-bonding characteristics and polarity to the substance that are analogous to water. Ethyl alcohol displays a highly nonideal behavior in numerous solutions, forming several azeotropes. The list of binary azeotropes of ethanol is long, including acetonitrile, benzene, carbon disulfide, chloroform, ethyl acetate, hexane, toluene, and water. See also **Azeotropic System**.

Chemistry Ethyl alcohol reacts (1) with sodium metal, forming sodium ethoxide C_2H_5ONa plus hydrogen gas, (2) with phosphorus chloride, bromide, iodide, forming ethyl chloride, bromide, iodide, respectively, (3) with H_2SO_4 concentrated, forming at 100 °C ethyl hydrogen sulfate $C_2H_5OSO_2OH$, at 140 °C diethyl ether $(C_2H_5)_2O$, at 200 °C ethylene CH_2:CH_2, (4) with organic acids, warmed in the presence of H_2SO_4, forming esters, e.g., ethyl acetate $CH_3COOC_2H_5$, ethyl benzoate $C_2H_5COOC_2H_5$ (see various individual acids), (5) with magnesium methyl iodide in anhydrous ether (Grignard's solution), forming methane as in the case of primary alcohols, (6) with calcium chloride to form a solid addition compound $4C_2H_5OH \cdot CaCl_2$, which is decomposed by H_2O, (7) with oxygen, using sodium dichromate solution and H_2SO_4, to form acetaldehyde (and acetic acid), using air, in the presence of acetic bacteria, to form vinegar (dilute acetic acid along with the substances present in the alcohol used, e.g., wine, cider), (8) with HNO_3 (a) concentrated, free from nitrogen tetroxide, to form ethyl nitrate, (b) dilute to form glycollic acid, (c) concentrated acid containing nitrogen tetroxide (fuming HNO_3) explosive reaction, (9) with chlorine (or bromine) to form chloral CCl_3CHO (or bromal).

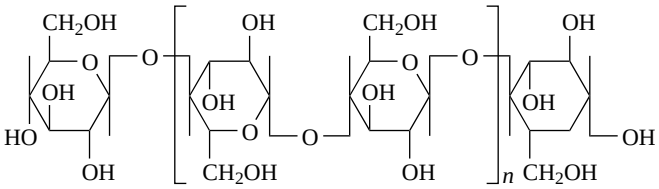
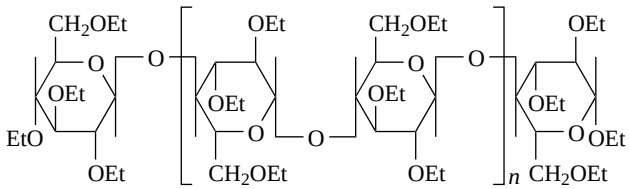
ETHYL CELLULOSE. [CAS: 9004-57-3] A versatile, thermoplastic cellulose ether that is compatible with a wide variety of solvent systems, resins, oils, and plasticizers. This versatility permits a wide diversity of end-product properties. It is an excellent film former as from a wide range of neat, lacquer, or dispersion formulations. Molded ethyl cellulose has excellent toughness, flexibility, and shock resistance. Useful temperature range is from about −40 to +100 °C. In the preparation of ethyl cellulose, wood pulp or cotton linters with a high alpha-cellulose content are reacted with ethyl chloride and sodium hydroxide. Structural formulas of cellulose and ethyl cellulose with complete (54.9%) ethoxyl substitution are:



Cellulose, $n > 500$



Tri-*O*-ethyl cellulose, $n = 50–150$; Et = CH_3CH_2

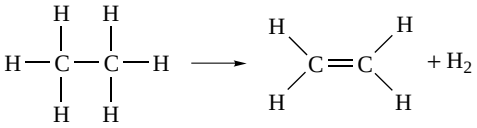
The natural color of ethyl cellulose is colorless to light amber, but it can be formulated into a wide range of transparent, translucent, and opaque colors. The material should be dried before molding because it is slightly hygroscopic. Compression molding temperatures range from 121–200 °C and pressures from 500–5,000 psi. Injection molding temperatures range from 175–260 °C and pressures from 8,000–32,000 psi. Strong acids decompose the material, but weak acids and strong alkalis have only a slight effect. Weak alkalis do not attack the material. Ethyl cellulose is soluble in a large number of organic solvents.

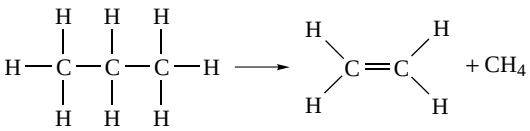
Among the commercial uses for ethyl cellulose are: strippable coating for metal parts, paper coatings, and in medicinal tablets. An interesting application is coating for bowling pins. Ethyl cellulose sheeting is tough, flexible, and transparent, yet sufficiently rigid to withstand rough handling.

ETHYL CHLORIDE. See **Chlorinated Organics**.

ETHYLENE. [CAS: 74-85-1] C_2H_4, formula weight 28.03, colorless gas with slight odor, normal bp −103.7 °C, critical pressure of 49.98 atmospheres, and critical temperature of 9.5 °C, density 1.26 grams per liter (0 °C and 760 mm), sp gr 0.97 (air = 1.0), very slightly soluble in H_2O, slightly soluble in alcohol. Ethylene burns when ignited in air with a luminous flame. The presence of ethylene in coal gas is chiefly responsible for the luminosity of the latter gas. Ethylene forms an explosive mixture with air and has a high fuel value, 1,615 Btu per cubic foot.

Even though there are few direct end-uses for ethylene, it is probably the most important petrochemical feedstock, both in terms of quantities used and economic value. Ethylene is the feedstock for ethylene oxide, ethylbenzene, ethyl chloride, ethylene dichloride, ethyl alcohol, and polyethylene, most of which, in turn, are used to produce hundreds of other end-products. Most ethylene is produced by steam cracking of ethane or propane.



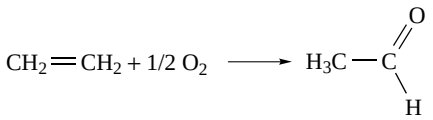


Ethylene also may be produced from other paraffinic or naphthenic hydrocarbons. The reactions are highly endothermic (34,400 kcal/kg mole of ethane cracked at approximately 900 °C) and proceed in the direction indicated at temperature exceeding approximately 620 °C without a catalyst.

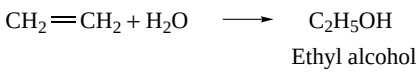
Ethylene is of importance as a petrochemical feedstock because of its great versatility in reacting to form several chemical intermediates. The double bond provides reactivity; the compound also has the ability to homopolymerize and copolymerize with other monomers. Some of the important reactions involving ethylene include:

Chlorination

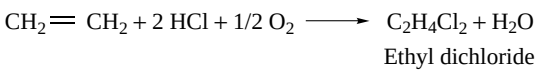
Oxidation



Hydration

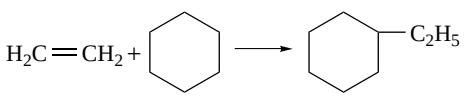


Oxychlorination



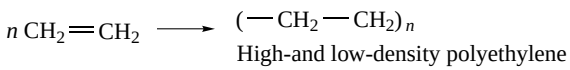
Ethylene dichloride is used for the production of vinyl chloride.

Alkylation

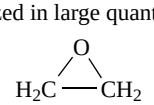


Ethyl benzene is used for the production of styrene.

Polymerization



Ethylene is also oxidized in large quantities to ethylene oxide:



At one time, ethylene was produced by the dehydration of ethyl alcohol over alumina.

Almost any naphthenic or paraffinic hydrocarbon heavier then methane can be steam-cracked to yield ethylene. The preferred feedstock in the United States has been ethane and/or propane recovered from natural gas, or from the volatile fractions of petroleum. However, because of long-term uncertainties pertaining to natural gas, many producers have been turning to heavier petroleum fractions, such as gas oils, as feedstock. The consumption of ethylene throughout the free world is estimated to be about 40×10^9 pounds per year.

Ethylene reacts: (1) with the halogens to form substitution halides; (2) with hypochlorous and hypobromous acid to form ethylene chlorohydrin or ethylene bromohydrin, respectively; (3) with hydrogen iodide or bromide (not chloride) to form ethyl iodide or ethyl bromide; (4) with hydrogen, in the presence of a catalyst, e.g., finely divided nickel at 150 °C, to form ethane; (5) with concentrated sulfuric acid at 160 °C to form ethyl hydrogen sulfate; and (6) with potassium permanganate to form ethylene glycol, although glycol is preferably made from ethylene dichloride or chlorohydrin.

In addition to its uses in the preparation of intermediates for a large variety of petrochemical reactions, ethylene is used as an anesthetic, as a fuel with oxygen for high-temperature flames, and as a coloring and ripening agent for citrus fruits and tomatoes. Ethylene chlorohydrin is used as an agent for decreasing the dormant period of seeds. See also **Polyethylene**.

ETHYLENE DICHLORIDE. See **Chlorinated Organics**.

ETHYLENE GLYCOL. [CAS: 107-21-1] This compound, $HOCH_2CH_2OH$, is traditionally associated with its use as a type of permanent antifreeze for internal-combustion engine cooling systems. However, since the early 1960s, large tonnages of ethylene glycol have been used in the production of polyesters for fibers, films, and coatings. The compound also finds important uses in hydraulic fluids, in the manufacture of low freezing-point explosives, glycol ethers, and deicing solutions. Di-and triethylene glycols are important coproducts usually produced in the manufacture of ethylene glycol. Diethylene glycol, $HOCH_2CH_2OCH_2CH_2OH$, is used in the production of unsaturated polyester resins and polyester polyols for polyurethane-resin manufacture, as well as in the textile industry as a conditioning agent and lubricant for numerous synthetic and natural fibers. It is also used as an extraction solvent in petroleum processing, as a desiccant in natural gas processing, and in the manufacture of some plasticizers and surfactants. Triethylene glycol,

$$HOCH_2CH_2OCH_2CH_2OCH_2CH_2OH,$$

finds principal use in the dehydration of natural gas and as a humectant.

In one process for the manufacture of the aforementioned glycols, ethylene oxide is formed by direct oxidation of ethylene with oxygen over a silver catalyst. After purification, the stabilized ethylene oxide is mixed with a large excess of water, preheated, and fed to an ethylene oxide reactor. Here the ethylene oxide and water react under high temperature and high pressure to form principally ethylene glycol, with the other aforementioned glycols as coproducts. The crude glycols are dehydrated and then recovered individually as highly pure overhead streams from a series of vacuum-operated purification columns.

Principal properties of the glycols are summarized in Table 1.

TABLE 1. PROPERTIES OF ETHYLENE, DIETHYLENE, AND TRIETHYLENE GLYCOLS

	Ethylene Glycol	Diethylene Glycol	Triethylene Glycol
Molecular weight	62.07	106.12	150.17
Boiling point (760 mm Hg)	197.6 °C	245 °C	287.4 °C
Vapor pressure (20 °C)	0.06 mm Hg	<0.01 mm Hg	<0.01 mm Hg
Specific gravity (20 °C/20 °C)	1.1155	1.1184	1.1254
Freezing point in air (760 mm Hg)	−13 °C	83 °C	99 °C
Water solubility	- - - - - - - -	complete	- - - - - - - -

Source: Glycols, Shell Chemical Company Bull. IC: 67– 58.

ETHYLENE OXIDE. [CAS: 75-21-1] $[(CH_2)_2]0$, formula weight 44.05, liquid, mp $-111.3\,^{\circ}C$, bp $13.5\,^{\circ}C$, sp gr 0.887. The compound is miscible in all proportions with H_2O or alcohol and is very soluble in ether. Ethylene oxide is slowly decomposed by H_2O at standard conditions, converting into glycol $CH_2OH \cdot CH_2OH$. Ethylene oxide is a very high-tonnage chemical, approaching nearly 4 billion pounds annually. In terms of consumption, it is used as follows: (1) 60% for manufacture of ethylene glycol, an antifreeze compound, as well as a raw material for production of polyethylene terephthalate (used in the manufacture of polyester fibers); (2) 12% for preparation of surfactants; (3) 8% for the manufacture of ethanolamines; (4) 10% for production of ethylene glycols which are used in plasticizers, solvents, and lubricants; and (5) 10% for making glycol ethers, which are used as jet-fuel additives and solvents. See also **Rocket Propellants**; and **Antimicrobial Agents (Foods)**.

Direct oxidation of ethylene in the presence of a silver catalyst is the predominant large-scale process used: $CH_2 : CH_2 + \frac{1}{2}O_2 \rightarrow \langle(CH_2)_2\rangle O$. The yield is approximately 70% of the theoretical. For maximum yield, very careful temperature control is required, the yield dropping as the temperature climbs. The side reaction: $CH_2 : CH_2 \rightarrow 3CO_2 + 2H_2O$ is the main factor for reducing yield. Thus far, silver has proved to be the most effective catalyst. Several compounds have been investigated that can inhibit the side reaction and also be compatible with the catalyst. These compounds have included ethylene dichloride, ethylene dibromide, alcohol, amines, and organometallic compounds, but their success has been limited. Plants have been designed to use either air or pure oxygen for oxidation. Selection presents an interesting study in economics because (1) where air is used, a purge reactor and associated purge absorber are required (not required by the O_2 process), and (2) where O_2 is used, both a CO_2 removal system and an O_2-making facility are required. The trend is toward the oxygen system with the ethylene oxide plant located near an air-separation plant.

Studies that still are inconclusive have linked ethylene oxide with leukemia and stomach cancer. It is estimated that in the United States approximately 270,000 workers are routinely exposed to ethylene oxide. Comparatively high level exposures include 96,000 persons working in hospitals and an additional 21,000 persons who work in commercial medical supply sterilization facilities, as well as in the production of spices and pharmaceutical products. Since the 1950s, ethylene oxide has been used as a sterilizing agent.

Biochemically, ethylene oxide is a highly reactive epoxide and is a direct alkylating agent. Details of one study are given by K. Steenland, etal (National Institute for Occupational Safety and the National Cancer Institute) in the *New England J. Medicine*, **1402** (May 16,1991). The report concludes: "Although our study is the largest to date of workers exposed to ethylene oxide, the results for the relatively rare cancers of a priori interest are still limited by the small numbers of cases and perhaps limited by the short follow-up. Our findings are therefore not conclusive."

It has been established, however, that ethylene oxide is a potent mutagen and animal carcinogen.

ETHYLENE-VINYL ACETATE COPOLYMERS. Known as EVA copolymers, these materials are polyolefins that can be processed like other thermoplastics, but they approach rubbery materials in softness and elasticity. The resins meet regulatory requirements for use in direct contact with food in food-processing machinery and in packaging applications. They are used in a number of applications to replace plasticized polyvinyl chloride and rubber. EVA copolymers require no curing or plasticizer. Parts made from EVA have little or no odor. Their elasticity is permanent. The copolymers can be injection-, blow-, compression-, transfer- and rotationally molded or extruded into film, sheeting, pipe, and profiles. EVA copolymers offer advantages over polyvinyl chloride and rubber in that they have good clarity and gloss, stress-crack resistance, good barrier properties, low-temperature flexibility and toughness, good adhesive properties, and good resistance to ultraviolet radiation. Their main limitation is a comparatively low resistance to heat and solvents. The resins soften at a temperature of about $70\,^{\circ}C$. EVA copolymers are not attacked by alcohols, glycols, or weak organic acids. However, to a varying degree, the materials are attacked by chlorinated hydrocarbons, straight-chain paraffinic solvents, and benzene and its derivatives.

ETIOLATION. This is the effect of darkness on a living plant. It is a matter of common observation that plants grown in darkness contain little or no chlorophyll and so are nearly white. Green plants placed in darkness lose their chlorophyll. Eventually, when the food reserves are exhausted, the plant dies.

Besides the lack of chlorophyll, plants grown in the dark have other characteristics. In dicotyledons, the internodes of the stem become excessively elongated and very slender. The leaves fail to expand normally. In monocotyledons, the leaves become very long and usually very narrow, but the stem shows little change. Etiolated plants never bear flowers, unless the flower buds are well developed before the plants are darkened. See Fig. 1.

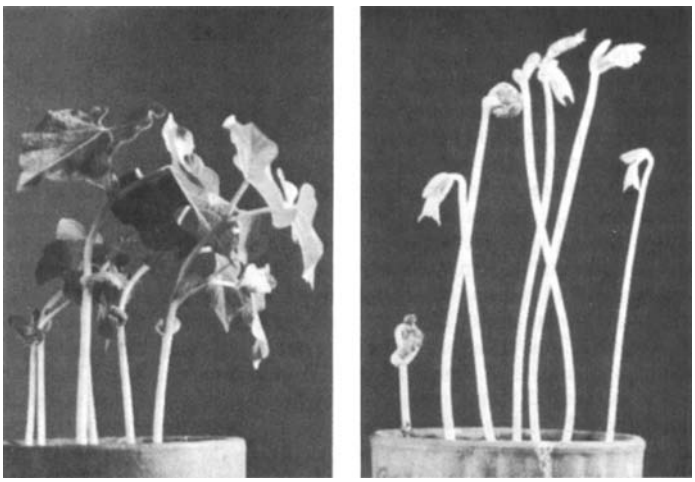


Fig. 1. Effect of darkness on the elongation of stems. The bean seedlings on the left were grown in the light; those on the right were grown in darkness.

Internally, the tissues are soft and lack strength, the cells being very large and having thin walls. Very little differentiation occurs, the conducting tissues being very much reduced. Leaves which form in darkness show very little of the structure characterizing a normal green leaf, but are almost entirely composed of loosely arranged parenchymatous cells.

See also **Plant Growth Modification and Regulation**.

ETIOLOGY. Knowledge of the cause of any disease or abnormal condition.

EUCALYPTUS TREES. Of the family *Myrtiaceae* (myrtle family), eucalyptus or gum trees are of the genus *Eucalyptus* and are native to Australasia. The tallest trees in Australia are eucalyptus and the *E. regnans* is regarded as the tallest of the nonconifers anywhere in the world. Eucalyptus trees, notably the blue gum (*E. globulus*), were introduced into California in the 1880s, whereupon it immediately thrived. This same species was introduced into Ethiopia in the late 1800s, where it also has fared well and much accepted because of a general lack of timber in that area. Lines of eucalyptus trees on the borders of citrus orchards in California are a common sight. It also has been reported that eucalyptus trees have been successful in reducing the occurrence of mosquitoes in marshy areas, the trees assisting in dewatering wet, boggy soil. There are some 600 species of eucalyptus, many of which are quite localized. Thus, generalization are difficult. Some of the more important species include:

Blue gum	*E. globulus*
E. caesia	
Cider gum	*E. gunnii*
Ghost gum	*E. papuana*
E. leucoxylon "Rosea"	
Lemon-scented gum	*E. citriodora*
E. miniata	
E. obliqua	
Red-flowering gum	*E. ficifolia*
E. regnans	
Red-flowering gum	*E. filifolia*
River red gum	*E. camaldulensis*
Snow gum	*E. niphophila*

TABLE 1. RECORD EUCALYPTUS TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location
	Inches	Centimeters	Feet	Meters	Feet	Meters	
Bluegum eucalyptus (1998) (*Eucalpytus globulus*)	461	1170	135	41.1	131	39.9	California
Longbeak eucalyptus (1995) (*Eucalpytus camaldulensis*)	342	869	130	39.6	105	32	Arizona

[1]From the "National Register of Big Trees," American Forests (by permission).
[2]At 4.5 feet (1.4 meters).

Spinning gum	*E. perriniana*
Tasmanian snow gum	*E. coccifera*
Woodward's gum	*E. woodwardii*

The red-flowering gum is exceedingly showy when in bloom. Not a tall tree, this species seldom exceeds 50 feet (15 meters) in height. In season, masses of bright-red blossoms in large and heavy clusters nearly cover the tree. The clusters are from 6 to 10 inches (15.2 to 25.4 centimeters) across. Where trees are planted along pathways, the massive blossoms create clearing problems.

The blue gum has a blue-gray bark, quite smooth. The tree may exceed 300 feet (90 meters) in height. The leaf is dark green, 6 to 12 inches (15.2 to 30.4 centimeters) long and about $1\frac{1}{2}$ inches (3.8 centimeters) broad. Growth is rapid and long periods of drought can be withstood. It will survive temperatures as low as 20 °F (4.4 °C) for short periods. Although the best known of the species introduced into California, there are at least 80 species of eucalyptus growing in the state. Other species include: The white gum or manna gum (*E. viminalis*) with a gray-white bark and height of from 50 to 60 feet (15 to 18 meters). The leaf is from 4 to 8 inches (10 to 20.3 centimeters) in length. The tree grows fast and may have a girth of up to 3 feet (0.9 meters) within a 12-year period. The tree can tolerate poor soil. The dollar-leaf eucalyptus (*E. pulverulenta*) has blue-green leaves, essentially round in shape, and from 2 to 3 inches (5 to 7.6 centimeters) across. The tree grows to about 30 feet (9 meters) in height. The stalk is narrow, ranging up to about $2\frac{1}{2}$ inches (6.4 centimeters). The ornamental foliage is frequently used by florists and artists.

The Tasmanian snow gum is planted in England. The snow gum can withstand the climes of Mount Kosciusko (New South Wales) up to an altitude of 7000 feet (2100 meters).

The record eucalyptus trees complied by American Forests are shown in Table 1.

Eucalyptus oil, an essential oil, is derived from the leaves of several species of these trees. The oil is used in various medicinal and household preparations.

An Energy Tree? In 1902, the Secretary of Agriculture (Theodore Roosevelt Administration) commented, "The phenomenally rapid growth of the eucalyptus and the special adaptation of many species to dry climates render these trees of particular economic importance to the nation." In fact, the eucalyptus had many ardent supporters in the 1850s, shortly after its introduction into the United States. Unlike some trees and shrubs that have been introduced enthusiastically to the nation only to "backfire" by creating problems of their own (see also **Casuarina Tree**; **Kudzu (Pueraria lobata)**; **Melaleuca Tree** for examples), the eucalyptus is still regarded in a positive way.

The latest recognized appeal of the eucalyptus is as a source of energy. Other industrial uses (as lumber and timber) in the United States have not been outstanding, but the Australians have been using the wood for decades in connection with shipbuilding, paper, fencing, and telegraph posts, among others. Among trees being studied in the United States as wood energy sources (because the day of the renewable energy resources will reawaken), numerous species of eucalyptus are being investigated. Objectives are to determine which species are able to grow quickly and dependably and in what geographical areas — so that transportation of wood fuel costs could be minimized. As observed by R.B. Pearce (*American Forests*, 30–34, January 1983), "Eucalyptus trees are ideal for short-rotation biomass production. The tree can establish a niche in any temperate climate, dry or wet, and is adaptable to the most improverished soil conditions. Most species can outproduce all other fuel stocks currently being studied (including many agricultural crops). The *Sydney bluegum* (*E. saligna*) can easily provide ten metric tons of oven-dried wood per acre (per 0.4 hectare) per year. And because most eucalyptus coppice (sprout from stumps), they can be harvested as often as twice a year without the need to replant. Unfortunately, a low tolerance to frost limits the distribution of the eucalyptus to California's coasts and lowland valleys, and to the warmer regions of Florida, Georgia, and the Carolinas."

EUCLASE. The mineral euclase is a silicate of beryllium and aluminum corresponding to the formula $BeA1SiO_4(OH)$, which crystallizes in the monoclinic system. It has a perfect prismatic cleavage; hardness, 7.5; specific gravity, 3.1; luster, vitreous; is colorless to sea-green or blue. It has been used to a very slight extent for jewelry as its transparent crystals somewhat resemble the aquamarine. Euclase occurs in the Minas Gerais region, Brazil, associated with topaz and beryl, and also in the Ural Mountains, where it is found in gold-bearing sands. The name euclase is derived from the Greek, meaning easiness and fracture, in reference to its easily cleaved crystals.

EUCLID (Born about 330 B.C. Died about 275 B.C.). Not much is known about Euclid's life except that he taught at Alexandria in Egypt. He was a mathematician of antiquity whose treatise on ***The Elements*** was a compilation of knowledge that influenced mathematical teaching for 2000 years. He developed Euclidean Geometry, which held until the 1800's during which time other kinds were found.

See also **Algorithm**; **Euclidean Space**; and **Geometry**.

J. M. I.

EUCLIDEAN GEOMETRY. See **Geometry**.

EUCLIDEAN SPACE. A generalization of the algebraic, geometrical and topological properties of the line, the plane, and three-dimensional space to n dimensions.

A Euclidean n-space is an n-dimensional linear space provided with a scalar product. A concrete realization of Euclidean n-space is the set of n-tuples $(\lambda_1, \lambda_2, \ldots, \lambda_n)$ of real numbers with the scalar product of $(\lambda_1, \lambda_2, \ldots, \lambda_n)$ and $(\mu_1, \mu_2, \ldots, \mu_n)$ defined as $\lambda_1\mu_1 + \lambda_2\mu_2 + \cdots + \lambda_n\mu_n$.

In mathematical models for physical systems, it is often necessary to consider spaces having more than three dimensions; for example, six dimensions are needed to locate two particles in Euclidean three space.

EUCLID'S ALGORITHM. See **Algorithm**.

EUDIOMETER. A graduated tube closed at one end. In one form, two platinum wires are sealed so that a spark may be passed through the contents of the tube; used to measure the volume changes in the combustion of gases.

EULER ANGLE. One of three parameters describing the orientation of a rigid body relative to a Cartesian coordinate system (x, y, z) fixed in space. Suppose another coordinate system (x', y', z') is fixed in the body. Then the two systems may be made coincident by three successive rotations, applied in the appropriate order, and the three angles are the Euler angles.

See also **Coordinate System**.

EULER-CHELPIN, HANS KARL AUGUST SIMON VON (1873–1964). Hans Euler-Chelpin was a German- born Swedish biochemist who clarified the role played by enzymes in alcoholic fermentation.

Euler-Chelpin, the son of a Bavarian army captain who descended from the same family lineage as the Swiss mathematician Leonhard Euler, became interested in the theory of colors and the spectrum as an art student in Munich (1891–1893), and so decided to study science. After graduation from the University of Berlin (1895) and two years at Göttingen, he became assistant to Svante Arrhenius at Stockholm, taking a qualification in physical chemistry in 1898. He took Swedish citizenship in 1902 (but served Germany during both world wars), and became Professor of General and Organic Chemistry at the University of Stockholm in 1906. See also **Arrhenius, Svante August (1859–1927)**.

An early interest in inorganic catalysis was soon replaced by biochemical studies: Euler-Chelpin investigated plant chemistry, and the enzymes associated with fermentation (*Chemie der Hefe und der alkoholischen Gärung*, 1915). In 1923 he took up a problem derived from the work of Arthur Harden, who had earlier shown that yeast enzymes contain an easily removable nonprotein part, a coenzyme named cozymase. By 1929 Euler-Chelpin had clarified its role in fermentation, and he and Harden shared the Nobel Prize for chemistry. See also **Harden, Arthur (1865–1940)**.

Euler-Chelpin was the author of a textbook on enzymes, *Chemie der Enzyme*, of which there were several editions. Despite his appointment in 1929 as director of a new biochemical institute at the University of Stockholm, he continued to publish research papers at a remarkable pace. A father of nine, his son Ulf von Euler shared the Nobel Prize for Physiology or Medicine in 1970.

EULERIAN COORDINATES. Any system of coordinates in which properties of a fluid are assigned to points in space at each given time, without attempt to identify individual fluid parcels from one time to the next. Since most observations in meteorology are made locally at specified time intervals, an Eulerian system is usually, though by no means always, more convenient. A sequence of synoptic charts is an Eulerian representation of the data.

EULER, LEONHARD (1707–1783). Euler was a Swiss mathematician who studied under Bernoulli. He published over 800 different books and papers on mathematics, physics, and astronomy. After he lost his eyesight, he was still able to compute complex calculations in his head.

See also **Euler Angle**; **Eulerian Coordinates**; **Euler-Mascheroni Constant**; and **Number Theory**.

J. M. I.

EULER-MASCHERONI CONSTANT. A number, also often called simply Euler's constant, which occurs in one definition of the gamma function. It can be defined by several equivalent infinite integrals, one example being

$$C = \int_{\infty}^{0} e^{-t} \ln t \, dt$$

Its numerical value is 0.577215665 . . . but the quantity $\gamma = 1.781072\ldots$, defined by $\ln \gamma = C$ is sometimes defined as the Euler-Mascheroni constant.

See also **Gamma Function**.

EUPHORBIACEAE. Also known as the spurge family, this is a large family of usually cactus-like trees and shrubs which often yield a milky juice or latex. They occur in many tropical and temperate regions. There are a few herbaceous species, especially in cooler regions. Many of the tropical species are interesting xerophytes, plants capable of enduring the driest climates. Often these have a habit very similar to that of species of cactus, with which they may easily be confused, especially if not in flower. However, nearly all members of the spurge family contain a milky juice which exudes from them when the surface is cut or broken. This milky juice, or latex, will readily distinguish them from cacti, which lack latex. Leaves, when present, are usually alternate and have stipules. In many species, such as the frequently cultivated *Euphorbia splendens*, or "crown of thorns," the leaves soon drop off, leaving a spine-covered stem. In one genus, *Phyllanthus*, leaves are frequently reduced to minute scales, with the stem flattened and green; in these the small pinkish flowers are borne around the edge of the flattened stem. In some species of *Euphorbia* the leaves near the top of the stem become brilliantly colored, as in *Euphorbia pulcherrima*, the poinsettia, where they are bright red. Such leaves, surrounding the inconspicuous flower masses, are often mistaken for parts of the flower.

The inflorescence, in members of this family, is often very complex. In many species the individual flowers are crowded together in such a way as collectively to resemble a single large flower. The flowers are unisexual. The plants are either monoecious or dioecious. In many cases the flowers entirely lack both calyx and corolla, in others a calyx is present, but no corolla, while in some both calyx and corolla are present. They are regular flowers with the perianth commonly 5-parted. The number of stamens varies from one to many; in many cases, stamens are variously united; in some, as in the castor bean, they are branched. The ovary is usually 3-celled, with one or two ovules in each cell. The fruit is a capsule, which when mature often opens with considerable force, throwing the seeds out, often to considerable distances. The seeds have an abundant endosperm and a caruncle.

Among the members of this family are some plants of great economic importance. Many others are poisonous plants.

Hevea brasiliensis, the Para rubber plant, is perhaps the most valuable member. Species of *Ricinus* supply castor oil. Species of *Manihot*, a South American genus, yield cassava or mandioc, a starchy foodstuff, prepared from the large roots. *Manihot esculenta*, for instance, has long been cultivated in Brazil. It is a large, somewhat bushy herb with long-petioled leaves, the smooth blades of which are deeply cleft into 3–7 lobes. The roots, which have the appearance of sweet potatoes, are eaten in much the same way as sweet potatoes. Grated, they yield a starchy product used like bread. From the roots tapioca may be prepared. The poisonous principle, which is present in many species of *Manihot*, is removed by squeezing or destroyed by heating. From other species of this genus may be obtained, by tapping, a milky juice which is a source of rubber. See also **Rubber (Natural)**.

Hura crepitans, the sandbox tree, is another member of the family of some slight commercial value. The plant is a fairly large tree the stem of which is covered with short, sharp spines, and bears long-petioled toothed leaves. The fruit is composed of numerous hard carpels which, when mature, explode violently, throwing the seeds out forcibly. These fruits, about 3 inches (7.5 centimeters) in diameter, were formerly gathered and wired to prevent bursting. When dry they were used as containers for the fine sand, which was then used to blot ink — hence the common name of the tree. The wood of the tree is used locally, but rarely exported. The milky juice of the tree is very poisonous. This juice, mixed with meal or similar substances, and thrown into the waters of a stream or lake, stupefies the fish present therein, so that they may be readily captured. The poison does not render the fish dangerous for human consumption.

Several species of *Croton* yield important purgative drugs. *Croton eluteria* gives Cascarilla bark, used as a tonic.

Jatropha curcas, a small shrub or tree, bears egg-shaped green fruits which contain a high percentage of an odorless oil called "curcas" oil, used in making paints, as a lubricant, and in soapmaking. From the leaves of this tree, natives of the Philippine Islands prepare a fish poison used in much the same way as that obtained from *Hura*.

Aleurites are tropical trees bearing small many-seeded fruits extremely rich in oil. *Aleurites triloba*, the candlenut of the orient, produces a fruit extensively used for food and for light. *Aleurites cordata*, a native of China, is the "varnish-tree." *Aleurites fordii* yields tung oil.

EUPHOTIC ZONE. The layer of a body of water that receives ample sunlight for the photosynthetic processes of plants. The depth of this layer varies with the water's extinction coefficient, the angle of incidence of the sunlight, length of a day, and cloudiness; but it is usually 80 meters or more. The depth of compensation is the lower boundary of the euphotic zone. See also **Ecology**.

EUROPEAN CORN BORER *(Insecta, Lepidoptera).* A small moth, *Pyrausta nubilalis*, whose larva bores in the stems of plants, especially Indian corn. The species is closely related to certain North American moths and was first noticed as a pest in the eastern part of the United States about 1920. Since then it has spread westward.

EUROPIUM. [CAS: 7440-53-1] Chemical element symbol Eu, at. no. 63, at. wt. 151.96, sixth in the Lanthanide Series in the periodic table, mp 822 °C, bp 1529 °C, density 5.245 g/cm^3 (20 °C). Elemental europium has a body-centered cubic crystal structure at 25 °C. The pure metallic europium is silver-gray in color under vacuum, but oxidizes readily in air and must be handled in an inert atmosphere. Europium is very soft as compared with the other rare-earth metals. Two stable isotopes of the element occur naturally ^{151}Eu and ^{153}Eu. Upon absorption of thermal neutrons, ^{151}Eu forms ^{152}Eu with a half-life of 13 years; ^{153}Eu forms ^{154}Eu with a half-life of 16 years. The latter further decays to ^{155}Eu with a half-life of 1.7 years. In terms of abundance, europium is present on the average of 1.2 ppm in the earth's crust, making its potential availability greater than antimony, bismuth, or cadmium. The element was first identified by Sir William Crookes in 1889. Europium dissolves readily in dilute mineral acids and reacts with H_2O at room temperature. The metal is not known to be toxic but because of its high reactivity in air, great care in handling is mandatory. Electronic configuration

$$1s^2 2s^2 2p^6 3s^2 2p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^6 5fs^2 5p^6 5d^1 6s^1$$

Ionic radius Eu^{2+} 1.09 Å, Eu^{3+} 0.950 Å. Metallic radius 1.995 Å. First ionization potential 5.67 eV; second 11.25 eV. Oxidation potential $Eu^{2+} \rightarrow Eu^{3+} + e^-$, 0.43 V. Other important physical properties of europium are given under **Rare-Earth Elements and Metals**.

Europium occurs in the rare-earth fluocarbonate mineral bastnasite, mainly found in southern California. The mineral contains between 0.09 and 0.11% Eu_2O_3. Other minerals, such as xenotime and monazite, also contain europium compounds, and sometimes they are used as sources of the element.

Because of the desirable nuclear properties of the element, europium has received serious consideration for the construction of nuclear reactor hardware. Earlier commercial unavailability of the element, however, favored the use of other materials. Some small reactors have been constructed in which europium molybdate has been the major control-rod component. With much increased availability of the metal in recent years, the prospect of further usage of europium in reactor design are good. A europium-activated yttrium orthovanadate, Eu:YVO_4, has shown promise as a red phosphor for commercial television. An increase of 40% in light output has been claimed. With this system, the average color television set would require about $\frac{1}{2}$ g of Eu_2O_3 and 6 g of Y_2O_3. The stimulus resulting from this discovery resulted in the development of other new phosphors involving europium in various host matrices. These new materials have been used in high-intensity mercury-vapor lamps, general-purpose fluorescent lamps, x-ray screens, charged-particle detectors, and neutron scintillators. In some optically read memory systems, ferromagnetic europium chalcogenides (sulfides, selenides, and tellurides) have been used. Other electronic and semiconductor uses of europium are under serious investigation.

K.A. GSCHNEIDNER, Jr., Iowa State University, Ames, IA

EUROS. See **Winds and Air Movement**.

EUSTACHIAN TUBE. A slender canal between the pharynx and the middle ear of vertebrates. It permits the equalization of pressure on the two surfaces of the eardrum. See also **Hearing and the Ear**.

EUTAXIC. A term proposed by Keyes in 1901 for obviously stratified sedimentary ore deposits as contrasted with those which are unstratified. The latter he designated as ataxic.

EUTECTIC. An eutectic reaction is a reversible isothermal transformation in which, during cooling, a single liquid phase is transformed into two or more solid phases, the number of solid phases being equal to the number of components. In a given alloy system, at a fixed pressure, all phases will have fixed compositions during the isothermal transformation. The temperatures at which the freezing occurs is known as the eutectic temperature, while the composition of the liquid phase is called the eutectic composition. On a temperature-composition binary phase diagram, the eutectic point is determined by the eutectic composition and the eutectic temperature. In general, an alloy of the eutectic composition freezes at a minimum temperature. For this reason, eutectic compositions, or compositions close to the eutectic, are frequently used in low melting point solders.

By a similar usage in petrology, a eutectic is a discrete mixture of two or more minerals, in definite proportions, which have simultaneously crystallized from the mutual solution of their constituents. The eutectic point is the lowest temperature at any given pressure at which the above physical-chemical process may take place. The eutectic ratio is the ratio by weight of two minerals that originate by the above process.

EUTECTOID. This is a phase transformation analogous to an eutectic where a single solid phase, instead of a liquid phase, is transformed into two or more different solid phases. The number of solid phases in the resulting eutectoid structure is equal to the number of components in the system. Under very slow cooling, the eutectoid transformation should occur at the eutectoid temperature. However, due to the sluggishness of solid state transformations, there is usually some hysteresis with the transformation temperature depressed on cooling and raised on heating. Under equilibrium conditions, the compositions of the various phases are fixed in an eutectoid reaction just as they are in an eutectic transformation.

The best-known eutectoid reaction is that which occurs in steel where the austenite phase, stable at high temperatures, transforms into the eutectoid structure known as pearlite. In this transformation, the austenite phase, containing 0.8% carbon in solid solution, transforms to a mixture of ferrite (nearly pure body-centered cubic iron) and iron-carbide (Fe_3C). At atmospheric pressure, the equilibrium temperature for this reaction is 723 °C. This temperature is the eutectoid temperature.

In binary alloy systems, a eutectoid alloy is a mechanical mixture of two phases which form simultaneously from a solid solution when it cools through the eutectoid temperature. Alloys leaner or richer in one of the metals undergo transformation from the solid solution phase over a range of temperatures beginning above and ending at the eutectoid temperature. The structure of such alloys will consist of primary particles of one of the stable phases in addition to the eutectoid, for example ferrite and pearlite in low-carbon steel. See also **Iron Metals, Alloys, and Steels**.

EVAPORATION. The evaporation of a liquid consists in the escape from the main body of the liquid of those molecules which, in their thermal agitation, are moving with a sufficient speed to break through the surface tension. That is, evaporation is the escape of molecules whose kinetic energy exceeds the work function of cohesion at the liquid surface. Since only a small proportion of the molecules are at any instant located near enough to the surface and are moving in the proper direction to escape, the rate of the evaporation is limited. It is easy to see why it proceeds more rapidly with higher temperature, and why liquids of low surface tension are relatively volatile. Also, as the faster moving molecules emerge, those left behind have less average energy, and the temperature of the liquid is thereby lowered. If the evaporation takes place in a closed vessel, the escaping molecules accumulate as a vapor above the liquid. Many of them return to the liquid, such returns being more frequent, the greater the density and pressure of the vapor. Presently the processes of escape and return come to equilibrium; the vapor is then said to be "saturated," its density and pressure no longer increase, and the cooling effect ceases. Even a warm breeze cools the skin because it removes the evaporating perspiration and prevents saturation.

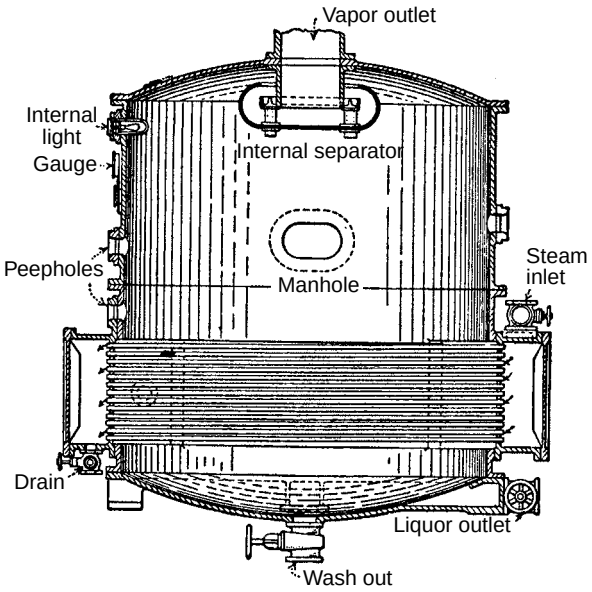

Fig. 1. Horizontal-tube evaporator.

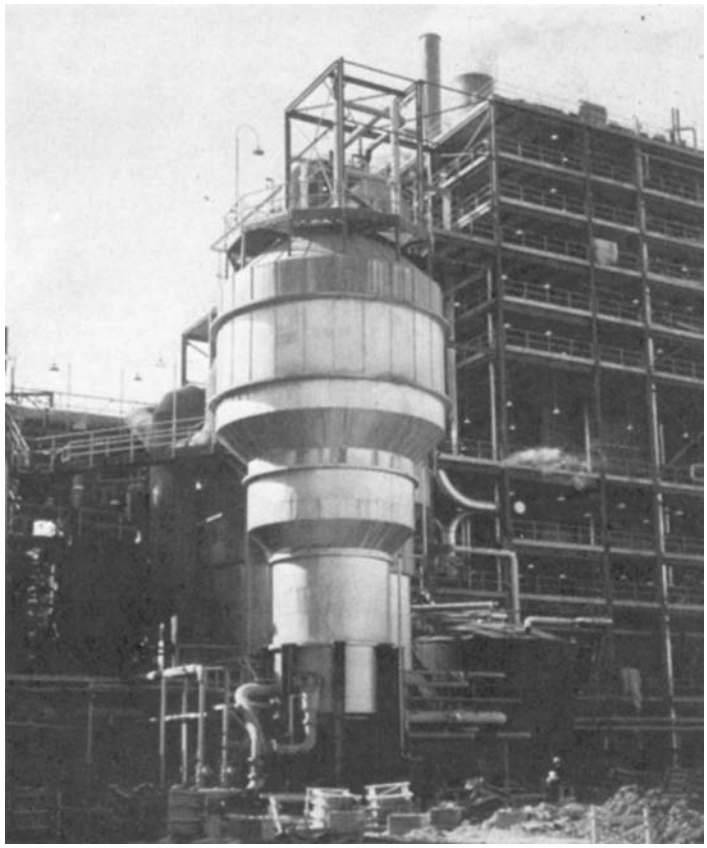

Fig. 2. The sixth-effect evaporator body of a multiple-effect evaporation system.

Evaporation is a major chemical engineering unit operation for bringing about separations of liquids and solids and, in particular, to recover the solute (such as a dissolved salt) from the solvent (frequently water). Usually, the main object of the separation is the solute. The pulp and paper industry is a large user of evaporation equipment. In pulp mills, after the digestion system, the pulp is leached with water and the chemical solids are dissolved out almost completely by a pulp-washing system. The recovered liquid from these operations is fed to an evaporator, generally at about 15% total dissolved solids content. The evaporator removes much of the water and in so doing concentrates the liquid to 55–65% total dissolved solids, whereupon the solution then can be further processed in a chemical recovery furnace. Other types of pulp processing also involve chemical-containing solutions that must be evaporated for recovery of valuable chemicals. Evaporation also is used extensively in the production of table and industrial salt (sodium chloride) as well as other salts, in caustic-chlorine production, in the phosphate industry, and in food processing. Evaporators can be large structures as the illustrations indicate.

Evaporation is, in principle, the same operation as plain distillation, with three modifications in practice. First, the vapor may or may not be recovered. Second, the residue in the evaporator may or may not contain solids. Third, vacuum evaporation is frequently used in a single compartment or in multiple stages, with each successive stage operated at an increasing vacuum, utilizing the heat of condensation of the vapor from the preceding stage. In multiple stage evaporators, there is a saving in the cost of heat and an increased expenditure for apparatus. Vacuum

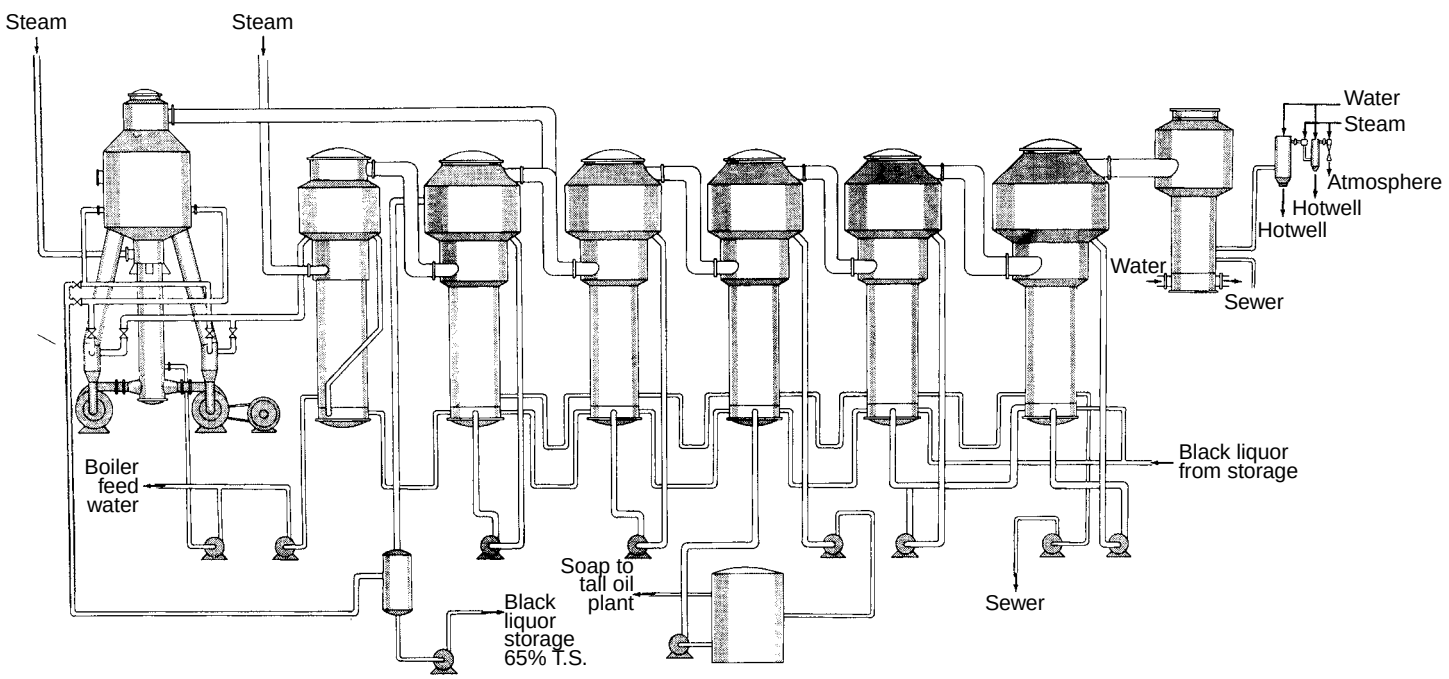

Fig. 3. Compound multiple-effect kraft mill evaporator.

evaporation is frequently utilized to lower the temperature to which a substance is subjected and thus avoid decomposition by passing a current of warm dry air over the substance. Combined high-vacuum and very low temperature evaporation or drying is practiced in the final removal of water vapor from frozen penicillin, due to the heat-sensitive nature of this material. Water vapor passes from the place of higher concentration, that is, the substance, to the place of lower concentration, that is, the air. Water vapor is thus removed from the substance. If oxygen of the air reacts with the substance, an inert gas such as nitrogen may be substituted for air.

An evaporator system may be single effect (Fig. 1), in which the steam is produced from one evaporator, or multiple effect, in which the steam is produced from several evaporators in series. In a multiple effect system, the vapor from one evaporator becomes the heating steam in the succeeding. Unusual conditions met in industrial or steam heating plants may require so large a fraction of make-up as to warrant double, triple, or quadruple effect evaporators. The central generating station ordinarily employs single effect and rarely requires more than a double effect system. The ratio vapor produced/steam used is about 0.8 for the single effect, 1.5 for the double effect, and 2.5 for the triple effect system. See Figs. 2 and 3. Evaporator feed is sometimes preheated to increase evaporator capacity.

Evaporators are classed as film, flash, or submerged-tube types. The first and last are steam-tube types; in the former the raw water trickles over the hot tubes, in the latter the tubes are entirely surrounded by the water being evaporated. The flash type produces steam by dropping the pressure on water at the saturation temperature. The excess heat flashes part of the water into steam, then the remainder is drawn off, reheated, and again flashed.

EVAPORATION (Meteorological). Evaporation of water is a solar energy driven phase change from liquid to vapor that maintains the hydrologic cycle by transferring liquid water at the earth's surface to water vapor in the atmosphere, where it may lift, condense, and precipitate to earth as liquid water. In this discussion, evaporation is defined to include the closely associated transpiration process as a subcategory. The coupled processes are often called as evapotranspiration, or ET, where transpiration focuses on the transport of liquid water through the plant roots, stem, and leaf prior to evaporation through the leave's stomata. Further, when the discussion does not make a clear distinction between potential and actual evaporation, potential should be assumed. Potential evaporation refers to the amount of water that available energy and diffusion processes can transfer into atmospheric vapor, which is typically greater then the amount actually transferred due to limits on soil water volumes and resistances in the path. See also **Evapotranspiration**.

Physical Controls on Evaporation

Evaporation is effectively a two-step process that first, requires that water changes phase to a vapor state and second, requires that the vapor is transported by advection and/or diffusion into unsaturated air. The phase change alone does not completely satisfy the requirement for evaporation when dynamic equilibrium exists at the boundary between liquid and vapor and condensation of the vapor saturated air returns liquid water to the surface to maintain no net water loss. Transport, therefore, ensures removal of the water vapor and a net loss of heat and mass from the liquid surface. In the vapor state, evaporated water is invisible to the human eye, which detects wavelengths between 0.4 and 0.7 μm, but is detectable in other areas of the electromagnetic spectrum. As such, though clouds are derived from and contain evaporated water, they are not vapor and instead reveal condensed water droplets that geometrically scatter light.

The first step in changing the phase of water from liquid to vapor requires an input of solar energy, which is stored at the surface and supports nighttime evaporation. Nearly 52% of solar energy absorbed at the earth's surface is used for vaporization. This energy is called latent heat of vaporization, or λ, and is a function of water temperature. When the phase changes directly from frozen water to vapor, known as sublimation, a greater amount of energy is required. Phase changes require energy to separate the hydrogen bond based, attractive intermolecular forces holding water molecules in an organized pattern and close proximity. Latent heat is a name that suggests dormant, or invisible, and is used to indicate that, unlike the measurable effect of sensible heat on air temperature, the solar energy used in evaporation remains 'hidden' from thermometer measurement.

As an example, at the standard pressure of 1013.3 milibar (mb), heating liquid water from 0 to 100 °C requires 4186.8 joules (J) of heat per kilogram of water per degree C temperature change and is detectable with a thermometer. In contrast, the latent heat of vaporization converting 100 °C water into 100 °C vapor does not have a measurable impact on water temperature. The latent heat, in megajoules per kilogram (MJ kg^{-1}), required per °C of water temperature, T, is given as

$$\lambda = 2.501 - 0.002361 \cdot T$$

It is apparent that the majority of heat input to evaporate water, whether at 0 °C or 99 °C, is that for the phase change. A relatively constant 1350 Js^{-1} m^{-2} stream of solar energy entering the earth's upper atmosphere provides energy to evaporate water just like a stove can boil and evaporate water. When 50% of this solar constant strikes the earth's surface after atmospheric attenuation (e.g., scattering and reflection), it requires approximately 1 hour and 10 minutes to generate the latent heat needed to evaporate 1 kg of water at 20 °C.

Latent heat, though not detectable as affecting air temperature, is stored with the vapor in greater vibrational, rotational, and translational movement of vapor molecules. The removal of this vapor from the liquid, therefore, causes a measurable loss of energy and temperature from the remaining liquid, producing a cooling effect. A familiar example of this process is that wet skin, from sweat or a shower, cools faster in moving rather than still air because the wind speeds evaporation that takes heat from the body. Knowing that heat is used for evaporation, it is now clear that a covered pot will boil faster than a counterpart uncovered pot do to a lower loss of heat to the net evaporation of water. Heat stored in vapor is later released back into the environment when the vapor vibrational speeds slow, and it condenses into water, called latent heat of condensation. When vapor passes directly to solid frozen water, called deposition, a greater amount of heat stored in rotational, vibrational, and translational molecular movement is released into the environment.

The second physical step in evaporation is transport by advection and/or diffusion, which provides the net movement of water molecules from the liquid water surface of soil, plants, or lakes to atmospheric vapor. Vapor and wind gradients exert the principal controls on removal of water vapor beyond the saturated layer of air that maintains condensation–evaporation equilibrium dynamics. Fundamental barriers to transport beyond the layer of dynamic equilibrium include stagnant air and saturated air above the evaporating surface, conditions readily created within and at the surface of soil and plant systems. Net evaporation therefore increases with steeper wind and saturation gradients, which are defined as the change in wind or saturation with distance above the evaporating surface. Work on fluid velocity and turbulence gradients in the mid-1900s by Prandtl and von Karman has been used to estimate momentum, sensible heat, and vapor transport from wind speed measurements.

Estimates of atmospheric wind and vapor conditions above the evaporating surface provide important data for estimating wind and saturation gradients and predicting barriers to vapor transport and net evaporation. Meteorological stations are frequently equipped with anemometers and thermometers at 2 meters (m) above the ground surface to help establish the wind and vapor gradients controlling evaporation. Wind profiles, it is assumed, begin with stagnant air at the no-slip boundary, or zero-plane displacement height, and increase logarithmically. In a landscape broken by tree canopies, a 2 m wind measurement may be inadequate to represent observations. Research has shown that dynamic turbulence and eddies created by such forested heterogeneity result in increased wind and evaporation rates that exceed the estimated atmospheric potential.

Based on Dalton's work on individual pressures of multiple atmospheric gases summing to the observed atmospheric pressure, vapor is often reported as a partial pressure and can be derived from measurements of temperature. In the following equation, vapor pressure is reported in kilopascals (kPa) and temperature in °C. Initially dry warm air can absorb more water than initially dry cold air before reaching saturation.

$$e = 0.6108 \exp\left(\frac{17.27T}{237.3 + T}\right)$$

The dry-bulb temperature is used to estimate the total amount of vapor the air could absorb prior to saturation; the dew point temperature represents the temperature to which the air must cool for total saturation. When the dry-bulb and dew point temperatures are equal, the air is fully saturated. The ratio of actual to saturated vapor pressures is the relative humidity. The dew point temperature is estimated by using a psychrometer that measures the difference between dry-bulb and wet-bulb thermometers, called the wet-bulb depression, together with lookup tables relating wet-bulb depression to dew point temperature. The dry-bulb is a normal thermometer measuring air temperature, but a moist piece of cloth typically covers the wet-bulb, and evaporation of the water from the cloth causes the temperature to drop. Chilled mirrors hygrometers, hair hygrometers, and vapor pressure sensors are also used to detect the vapor content in the air.

Evaporation Measurement

Evaporation is fundamental to both energy and water balances, yet despite the importance of evaporation to hydrologic assessment of the paths, quantities, and quality of water in the lithosphere, biosphere, and atmosphere, the complexity of the process has prevented easy or exact techniques for measuring and estimating it. The relative accuracy of yearly river basin evaporation estimates is high, as the estimate time frame and spatial area become smaller, but the simple application of energy and water balance models to solve for evaporation becomes less tractable. A variety of measurement and estimation techniques have been developed for these smaller scales, such as hourly, daily, and monthly evaporation from reservoirs, farm fields, and single plants.

In general, evaporative fluxes from the land surface are more difficult to measure than from open water, given that an immeasurable number of irregular, tiny and unique soil and leaf surfaces are involved in this phase change and that suction gradients draw water to this evaporating interface from unobserved reserves of unknown volume. Fluxes from open water, though relatively homogeneous, still provide challenges when subsurface inflows and outflows are poorly understood and significant and wind and water advected energy influencing evaporation is heterogeneously distributed. Hence, the numerous methods developed for estimating evaporation are categorized based on the type of surface, availability of water, and the importance of stored energy, water-advected energy, and air-advected energy.

Actual evaporation can be measured by using a water balance approach, a turbulent-transfer approach, a potential evaporation approach, or a water quality approach. The water balance approach can function with measurements of a mass balance being kept for a water pan, such as the Class-A Pan of the National Weather Service, a soil and plant system, such as in a weighing lysimeter, or of a small, enclosed atmosphere. Turbulent-transfer methods, which derive evaporation from estimates of momentum or heat flux, can provide estimates for larger heterogeneous areas, but assume that the air sampled by the field instrumentation used for the Bowen ratio or eddy-correlation method is well mixed to represent the upwind land area by a given fetch. Water quality methods include techniques that track concentrations of dissolved solids, which enrich when evaporation removes the water solvent, and isotope tracer studies that show heavier isotopes are enriched by preferred evaporation of lighter isotopes. Sap flow monitoring in trees provides another technique to measure the flux of water from the ground to the atmosphere.

Mathematical estimates of evaporation rates have been approached by using an equally wide variety of techniques and include temperature-based, aerodynamic-based, radiation-based, and combination-based methods. Temperature-based methods, such as the monthly time-step Thornthwaite equation, use air temperature and length of day, as well as an assumed humidity, to compute the potential evaporation, and they have been adapted to suit several different climates and regions. Aerodynamic methods assume that solar radiation is not limiting and consider only wind speed and turbulence as controls on the transport of water vapor away from the surface. Radiation-based methods likewise assume that wind turbulence and eddies are not limiting and use measured incoming radiation and the latent heat of vaporization to compute evaporation flux. A popular form of this equation is the Priestly–Taylor, which increased it by a factor of 30% to account for added aerodynamic transfer. The combination method, known most extensively for the Penman–Monteith equation, uses air temperature, net radiation, wind speed, and relative humidity vapor gradients to derive minute by minute and daily evaporation rates.

Hydrologic Impacts

Observations of terrestrial river discharge reveal that more water precipitates on land than evaporates from land and that more water evaporates from oceans than precipitates on oceans. Precipitation totals may vary from year to year, but evaporative demands are rather steady, which creates a greater relative fluctuation in river discharge than in precipitation. This is illustrated by considering a 20% decrease in annual precipitation from 100 to 80 cm (39 to 32 inches), where 50 cm (20 inches) went to evaporation in both years, and discharge dropped by 40% from 50 to 30 cm (20 to 12 inches). Evaporation and its impact on liquid and vapor water volumes and the partitioning of solar energy into latent and sensible heat create and maintain a range of climatic conditions, from microclimates on the scale of a tree canopy to macroclimates that describe the global distribution of plants.

The volume of water evaporated from the ocean and land surface is greatest at the meteorological equator, or intertropical convergence zone (ITCZ), and smallest at the poles, which is the result of a similar longitudinal distribution of insolation intensity. Sinking Hadley cell air at the 30° latitude belts, which warms to absorb greater amounts of water vapor, is the cause of a belt of deserts in this region. The distribution of incoming solar radiation, which is greatest at the equator and smallest at the poles, is the driving force explaining the meridional (across lines of latitude) distribution of evaporation. Wind transport of this evaporated vapor from the equatorial region to the midlatitudes and poles, where latent energy is released to the atmosphere as sensible heat during condensation, is one of only a few processes that help to maintain the earth's energy balance.

Global water balance numbers reveal that a relatively small volume of evaporated vapor resides in the atmosphere. The earth's atmosphere has a volume of 12,900 km^3, and contains just 0.001% of all global water. As evaporated vapor, it receives 71,000 $km^3\ yr^{-1}$ from land, 1000 $km^3\ yr^{-1}$ from lakes, and 505,000 $km^3\ yr^{-1}$ from oceans, and this flux rate into its total volume equals a residence time of 8.2 days, or just over a week before evaporated water precipitates. The atmospheric vapor precipitates at a volumetric rate of 577 $km^3\ yr^{-1}$, of which 119,000 $km^3\ yr^{-1}$ falls on land. Observation and estimation of river discharge at 47,000 $km^3\ yr^{-1}$ was used to deduce the amount evaporated from land, which is 61% evaporating, and this differs from the continental average of 64% reported in Table 1.

TABLE 1. CONTINENTAL AVERAGE ESTIMATED EVAPORATION

Continent	Area, km^2	Evaporation, mm yr^{-1}	Evaporation, %
Antarctica	14,100,000	28	Evaporation, 17
Europe	10,000,000	375	57
Asia	44,100,000	420	60
South America	17,900,000	946	60
North America	24,100,000	403	62
Africa	29,800,000	582	84
Australia	7,600,000	420	94
Total Land	148,900,000	480	64

For the continental United States, which contains deserts in Arizona and rain forests in Washington, the average annual percentage of precipitation converted to evaporation is approximately 62%. This value is similar to global patterns but varies considerably from that measured on other continents (see Table 1) and larger watersheds (see Table 2.)

TABLE 2. AVERAGE ESTIMATED EVAPORATION BASED ON STUDIES OF PRECIPITATION AND RUNOFF

Watershed by River Name	Continent [Nation(s)]	Basin Size, km^2	Evaporation,[a] %
Brahmaputra	Asia (Tibet/Bangladesh)	589,000	35
Irrawaddy	Asia (Burma)	431,000	40
Yangtzekiang	Asia (China)	1,970,000	50
Amazon	South America (six nations)	7,180,000	53
Orinoco	South America (Venezuela)	1,086,000	54
Lena	Asia (Russia)	2,430,000	54
Mekong	Asia (China)	795,000	57
Yenesei	Asia (Russia	2,599,000	58
Ganges	Asia (China)	1,073,000	58
Saint Lawrence	North America (Canada, U.S.)	1,030,000	67
Amur	Asia (Russia)	1,843,000	68
Congo	Africa (7 nations)	3,822,000	75
Ob	Asia (Russia)	2,950,000	76
Mississippi	North America (U.S.)	3,224,000	79
La Plata	South America (five nations)	2,650,000	80
Average	–	2,224,800	60

[a]Evaporation may include basin transfers because it was not directly measured but derived from precipitation and runoff measurements.

The agricultural impact of evaporation is both the cause of nutrient uptake and growth in plants, as well as the loss of soil water and plant stress. Maintenance of optimal water levels in the soil, called field capacity, when gravitational water has drained, is the goal of many irrigation projects. If irrigation causes evaporation to exceed local precipitation, then salts will be drawn to the soil surface, which often creates osmotic gradients at the root interface that kill the agricultural crop. Agricultural irrigation to satisfy the high evaporation demand of sunny agricultural land, such as California's Central Valley, has become a direct competitor for use as a public water supply.

EVAPORATION PAN. A type of evaporation gauge or evaporimeter; it is a pan used in the measurement of the evaporation of water into the atmosphere. The U.S. Weather Bureau evaporation pan (Class-A pan) is a cylindrical container fabricated of galvanized iron or other rust-resistant metal with a depth of 25.4 cm (10 in.) and a diameter of 121.9 cm (48 in.). The pan is accurately leveled at a site that is nearly flat, well sodded, and free from obstructions. The water level is maintained at between 5 and 7.5 cm (2 and 3 in.) below the top of the rim, and periodic measurements are made of the changes of the water level with the aid of a hook gauge set in the still well. When the water level drops to 17.8 cm (7 in.), the pan is refilled. Its average pan coefficient is about 0.7.

EVAPORITE. A sedimentary rock formed by precipitation from waters at the earth's surface. As described by Lowenstein (*Science*, **1090**, September 8, 1989), ancient evaporites have been used to track the chemistry of ancient surface waters, particularly seawater. Study of marine evaporites has led to the general (not unanimous) conclusion that the major elemental chemistry of seawater has not changed significantly during the last 600 million years.

EVAPOTRANSPIRATION. Liquid water from a surface can be transformed into water vapor by either evaporation or by transpiration. *Evaporation* is the process for converting liquid water to water vapor and removing it from the evaporating surface. *Transpiration* is the vaporization of water contained in plant tissues and the removal of vapor to the atmosphere through leaf stomata. Evaporation and transpiration occur simultaneously in cropped surfaces, and there is no easy way of quantifying the magnitude of each component. For practical applications, such as irrigation scheduling and irrigation system design, it has been more useful to consider both processes combined. The combination of these two processes is called *evapotranspiration*. The proportion of each component in a cropped surface is affected by factors such as vegetative cover, available water in the soil, and surface wetness. For an annual crop like corn, evaporation is the dominant component of evapotranspiration at the beginning of the season when the soil surface is exposed to solar radiation. As the crop grows and the canopy covers the surface, evaporation is minimized, and transpiration becomes the dominant component.

Evapotranspiration is an important process in agriculture and other natural sciences, such as hydrology, because it is an important component of the hydrologic cycle. It represents the water that is effectively lost from the earth's surface, and can no longer be controlled by humans. This type of water loss is often called consumptive use. Other types of processes that usually cause water losses from a given area on the earth's surface, such as runoff and deep percolation, do not involve a change in the physical state of water and therefore, water can still be controlled to some degree by humans. See also **Hydrologic Cycle**; and **Hydrology**.

Plants use water as a solvent and transport mechanism for nutrients and other chemicals, as a reagent for the chemical reactions involved in their physiological processes (such as photosynthesis), and as a component of cell cytoplasm, which allows plant tissues to stay turgid. Most of the water consumed by plants, however, is used in evapotranspiration. Evapotranspiration has the important function of regulating the temperature of plants, keeping them cool within a temperature range that favors growth. When the water supply in the soil is limited, for instance, plants respond by closing their stomata. This restricts the rate of evapotranspiration, and the temperature of the canopy tends to increase. This increase in canopy temperature has been used to estimate the rate of evapotranspiration of crops and as a way to detect crop water stress for irrigation scheduling. Because most of the water consumed by plants is lost in evapotranspiration, it takes a considerable amount of water for a crop to produce one unit weight of dry matter, as shown for different crops in (Fig. 1).

Researchers have shown that crop yield is often linearly related to crop evapotranspiration, up to the point where yield is limited by factors other than water. Therefore, if evapotranspiration is limited, yield is usually reduced. For this reason, in regions where rainfall is not sufficient to provide enough water for crops to keep evapotranspirating at a nonlimited rate, irrigation is required to obtain adequate crop yields. The nonlimited rate of evapotranspiration, however, can also be maintained by applying excess water. Application of excess water, however, has been linked to undesired side effects such as drainage problems, salinization of soils, soil erosion, and pollution of surface and groundwaters. In places where irrigation water needs to be pumped, pumping excess water also represents higher production cost. Therefore, it is considered ideal to schedule irrigation according to crop water

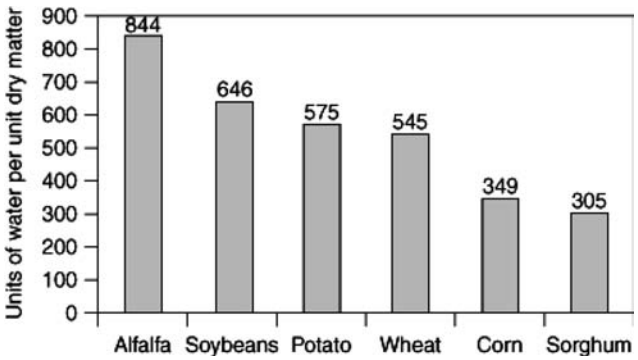

Fig. 1. Unit weight of evapotranspirated water needed per unit weight of dry matter produced by different crops (*adapted from Hoeft, Nafziger, Johnson and Aldrich Ref.*)

needs. This requires, among other things, good knowledge of crop evapotranspiration rates.

Measuring

Measuring the rate of evapotranspiration of crops and other surfaces is complex and is a subject that has attracted considerable research. Many methods have been devised to measure and estimate evapotranspiration. *Methods for measuring* evapotranspiration include the use of lysimeters, scintillometers, micrometeorological techniques such as the Bowen ratio and eddy covariance methods, and measurement of sap flow. Methods to measure evapotranspiration usually require expensive instrumentation and specialized training, and therefore have been confined mostly to research applications. Because of this, considerable effort has been devoted to develop methods for estimating evapotranspiration.

Estimating

Methods for estimating evapotranspiration include the use of different kinds of devices and a variety of equations. Devices such as evaporation pans, atmometers, and soil moisture monitoring devices have long been used to estimate evapotranspiration. The use of equations, however, is by far the most common method to estimate evapotranspiration. A great variety of equations have been proposed though the years, ranging from very simple to very complex models.

Simple models usually try to estimate evapotranspiration based on empirical relationships involving one or several meteorological variables. Complex models consider the physics governing the evapotranspiration process and try to include all factors that significantly contribute to the process. Complex models can be further divided into single-layer models and multiple-layer models. Single-layer models, such as the Penman–Monteith model, consider the crop canopy as a "big leaf," taking into account only processes that occur between the top of the canopy and the atmosphere. Multiple-layer models, on the other hand, also take into account those processes that take place below the crop canopy. Multiple-layer models are more theoretically sound than single-layer models, but their complexity makes them impractical for widespread use. Because a single-layer model is sufficiently accurate for most practical applications and relatively simple to apply, it has been proposed as the recommended method for estimating evapotranspiration .

Considerable effort has been made to estimate evapotranspiration using inputs obtained from remote sensing platforms, such as satellites or airplanes, and others have even tried to estimate evapotranspiration by measuring the flux of stable isotopes. Evapotranspiration, however, is more often estimated from equations that use meteorological data as input, as well as inputs that describe the characteristics of the evaporating surface. This is a convenient method because meteorological data are readily available in most places. Most nations and states support a network of meteorological stations and offer this information to the public in various ways. Meteorological data commonly used to estimate evapotranspiration include solar radiation, air temperature, relative humidity, and wind speed.

A detailed procedure for calculating evapotranspiration has been described by Allen et al.. The method involves a two-step process. One step consists of calculating the evapotranspiration rate of a reference crop, either clipped grass or alfalfa, which is usually known as reference evapotranspiration. In older literature, this was also called potential evapotranspiration. It represents a measure of the evaporating demand of the atmosphere for a short, cropped surface that effectively covers the ground, is growing healthily, and is not short of water, that is, a condition in which transpiration is not limited by stress, and the evapotranspiration demand of the atmosphere is met. The second step involves adjusting the reference evapotranspiration to match the conditions of the specific surface or crop being considered. This is done by calculating an adjustment factor, usually known as the crop coefficient. Depending on the accuracy required, calculating crop coefficients can also be a simple or complex process. Multiplying the reference evapotranspiration by the crop coefficient then results in the evapotranspiration rate for the crop or surface in question.

Requirements

Procedures used to estimate evapotranspiration try to simplify the complexities of the physical and physiological processes that affect evapotranspiration to a manageable number of quantifiable variables. They try to recognize that for the evapotranspiration process to take place, it is necessary to have

1. energy
2. water
3. space in the atmosphere to hold the water vapor
4. a transport mechanism for the water vapor to move from the surface to the atmosphere.

Evapotranspiration is an energy-driven process. It takes approximately 2.45 megajoules of energy to evaporate 1 kilogram (2.2 lbs) of water at 20 °C (68 °F). The sun supplies the energy needed for evapotranspiration from the earth's surface. Part of the solar energy that reaches the evaporating surface, however, is reflected back to the atmosphere and cannot be used for evapotranspiration. Of the energy that stays on the evaporating surface, known as net radiation, not all is used in evapotranspiration. The energy balance of a surface also includes energy that is absorbed or released by the soil (soil heat flux), by the air (latent heat flux), and that used in evapotranspiration (latent heat flux). All of these types of heat fluxes take place simultaneously from a given surface, and their proportions depend on the characteristics of the surface and weather conditions.

The amount of energy used for evapotranspiration includes short-wave radiation that comes directly from the sun, long-wave radiation or heat that comes from the surface, and advective heat that is transported horizontally by hot wind to the evaporating surface. The amount of energy available for evapotranspiration varies with latitude, day of the year, time of day, atmospheric conditions, and the characteristics of the surface itself. Figure 2 shows how the theoretical clear-sky solar radiation for different latitudes varies throughout the year. Figure 3 shows how measured solar radiation varies during the day and the effect of cloudiness in reducing the amount of solar energy that reaches the surface. As a general rule, the higher the amount of energy available at the evaporating surface, the higher the evapotranspiration rate, assuming that all other conditions required for evapotranspiration are met.

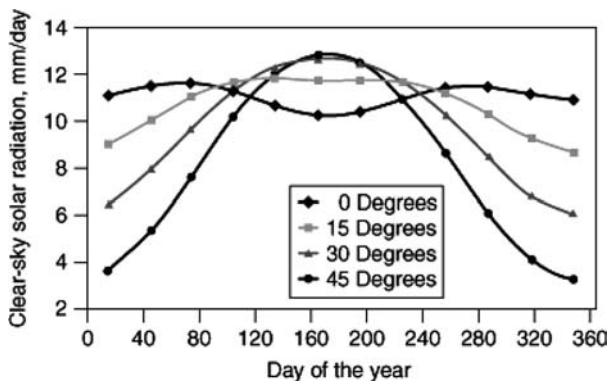

Fig. 2. Theoretical clear-sky solar radiation values for different northern latitudes and day of the year at sea level.

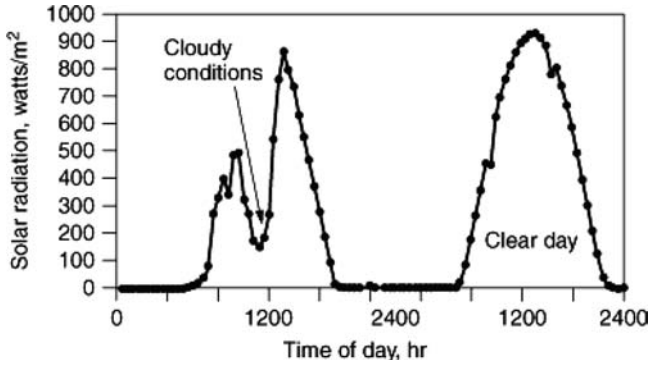

Fig. 3. Measured solar radiation in North Platte, NE, on July 15 and 16, 2001.

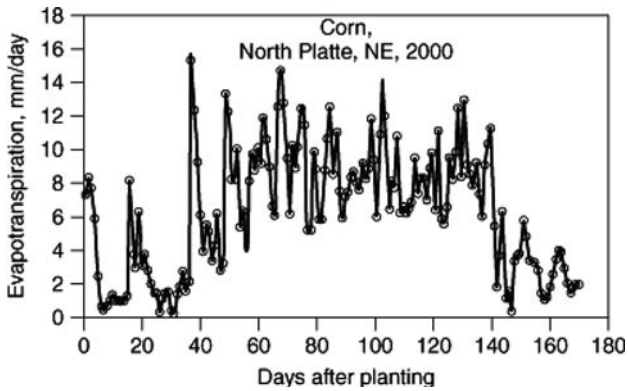

Fig. 4. Calculated daily evapotranspiration for corn in North Platte, NE, during the year 2000.

Water is the next essential requirement for evapotranspiration. If water is not available, the energy available to evaporate water is then used to heat the air and the soil. Under desert conditions, for instance, where energy is usually plentiful, but water is normally very limited, the evapotranspiration rate can be very small. Most of the energy is converted to sensible heat flux, soil heat flux, and a very small portion or none of the energy is converted to latent heat flux. Similarly, when crops are under water stress, the evapotranspiration rate is reduced.

Space in the atmosphere to hold the water vapor is also needed for evapotranspiration to proceed. When water is evaporated from a surface, the water vapor will travel to the atmosphere where it will be stored, provided that the atmosphere is not saturated. If the atmosphere is already saturated, it will not be able to store the additional water vapor, and evapotranspiration will be restricted. The drier the air in contact with the evaporating surface, the more evapotranspiration is enhanced. For this reason, the humidity of the air, usually expressed as relative humidity, is an important factor to consider when estimating evapotranspiration.

The last requirement for evapotranspiration is a transport mechanism for moving water vapor from the surface to the atmosphere. There are two basic transport mechanisms for water vapor. The first is turbulence. Turbulence is created when air moves horizontally over a rough surface. The friction created by the contact of the air with the rough elements of the surface creates a vertical component of the wind speed, which creates eddies of different sizes. The size of these eddies depends on the roughness of the surface and on the magnitude of the wind speed. These eddies carry the water vapor to the atmosphere. The other transport mechanism is buoyancy. Hot air is less dense that cold air; as the air close to the surface becomes hotter than the air above, it tends to ascend, carrying with it the water vapor. Turbulence is the most important transport mechanism in most instances, so wind speed is a very important factor in determining evapotranspiration. The higher the wind speed and the rougher the surface, the more turbulence, and the higher the evapotranspiration rate will be.

Magnitude

Evapotranspiration rates are most commonly expressed in units of water depth per unit time, such as millimeters per day (mm day^{-1}) or inches per month (in $months^{-1}$). Since it takes energy to evaporate water, water depths can also be expressed in terms of energy received per unit area. Therefore, evaportanspiration is often expressed in units of energy per unit area per unit time, such as watts per squared meter (w m^{-2}), or megajoules per squared meter per day (MJ m^{-2} day^{-1}). It can, however, also be expressed in units of energy per unit area, such as watts m^{-2}, or MJ m^{-2} day^{-1}. Many of the factors affecting evapotranspiration are so dynamic that the magnitude of the evapotranspiration rates for a given surface will vary from day to day, from place to place, and throughout the day. Figure 4 shows the calculated daily evapotranspiration rate for corn in North Platte, Nebraska, during the 2000 growing season. It shows the typical large variations in evapotranspiration rate that can be expected from day to day, as a result of normal daily changes in weather conditions. It also shows a seasonal pattern, as a response to the seasonal changes in available energy and to the changing water demand of the crop during its growing cycle.

EVECTION. A perturbation of the moon in its orbit due to the attraction of the sun. This results in an increase in the eccentricity of the moon's orbit when the sun passes the moon's line of apsides and a decrease when perpendicular to it. Evection amounts to 1 degree 15 minutes in the moon's longitude at maximum.

EVEN-EVEN NUCLEI. Atomic nuclei that contain an even number of protons and an even number of neutrons.

EVENT. A happening, represented by a point (x, y, z, t) in the space-time continuum. It is a fundamental assumption of the theory of relativity that all physical measurements reduce to observations of relations between events.

EVOLUTE. The evolute of a given curve is the locus of its centers of curvature. See also **Involute**.

EVOLUTION (Biological). (1) The development of an organism toward perfect or complete adaptation to environmental conditions to which it

has been exposed with the passage of time. (2) The theory that life on earth developed gradually from one or several simple organisms (appropriate molecules) to more complex organisms. This is sometimes called *organic evolution*. The term *evolutionary biology* is also used.

In contemplating the great diversity and vast numbers of species of life on earth, during post-Renaissance times, Linnaeus (1707–1778) and many of his contemporaries ascribed these to a concept of special creation — "there are just so many species as in the beginning the Infinite Being created."

In his *Philosophie Zoologique*, the French philosopher, Jean Baptiste de Lamarck, observed in 1809, "the existence in organisms of a built-in drive toward perfection; the capacity of organisms to become adapted to 'circumstances' [environment in modern terminology]; the frequent occurrence of spontaneous generation; and the inheritance of acquired characters, or traits."

The fourth of the foregoing observations was shown to be inaccurate, but about a half-century later, Darwin (1859) accepted the concept, i.e., "assumed that the use or disuse of a structure by one generation would be reflected in the next generation." Some other theorists who followed Lamarck and Darwin also accepted the validity of Lamarck's fourth observation and it remained for the German biologist, August Weissman (1834–1914), to stress the impossibility (or at least the improbability) of that observation. This constituted the first of several modifications of early hypotheses and the later theory, progressing from Lamarckism to Darwinism, to neo-Darwinism, and to the more recent synthetic theory and to the current conceptual developments.

Seldom stressed is the fact that, although the theory of evolution is some 120 years old (Darwinism) or 170 years old (Lamarckism), the theory, in terms of the research required to round out its full development and implications, is still in its infancy. Compared with the life sciences information bank of the late 20th century, the early theoretical endeavors were conducted in a scientific vacuum. Thus, the emergence of advanced genetics, cytology, molecular biology and numerous other sciences relative to evolutionary biology, have affected, and will continue to affect, those scholars who pursue the theory in their efforts to construct a continuum of events that led from a lifeless earth to living organisms and systems as we know them today.

The difficult tasks facing investigators in this field today are typified, in part, by the observations of one authority on the concept of chemical evolution of life: "The evolution of the genetic machinery is the step for which there are no laboratory models; hence one can speculate endlessly, unfettered by inconvenient facts. The complex genetic apparatus in present-day organisms is so universal that one has few clues as to what the apparatus may have looked like in its most primitive form." (R.E. Dickerson, 1978).

During the 1980s, there was a trend toward more effective comingling of various scientific disciplines in an effort to weave a tighter and more coherent network of information concerning the theory of evolution. These include, among many others, the improved integration of findings of paleontologists, archeologists, anthropologists — and chemists and physicists who have developed improved age-estimating and dating techniques. As pointed out by Woodruff (1980) in a review of Stanley's book (see reference list): "Paleontology is currently undergoing an exciting rejuvenation, and Stanley and his fellow paleobiologists (as they are now called) have introduced some scientific rigor into a traditionally descriptive field. Now, in place of inspired speculation, we see attempts to test hypotheses derived from theoretical population ecology against the extensive fossil record. . .. Evolutionary biologists can no longer ignore the fossil record on the ground that it is imperfect."

Possibly the most important conference on evolutionary biology held since the 1940s convened in Chicago in the fall of 1980. As reported (Lewin, 1980), the principal issues discussed at the meeting were (1) the tempo of evolution; (2) the mode of evolutionary change; and (3) the constraints on the physical form of new organisms. Dominating the field of evolutionary biology for several decades, the Modern Synthesis concept of evolution (so named by Julian Huxley in 1942) was reexamined in the light of many intervening years of progress in the biological sciences. In essence, this concept assumes that the pace of evolutionary change is slow, that the direction of evolutionary change is governed by natural selection involving small variations, and that the variants that survive are those that are environmentally superior. The proceedings are well encapsulated by Lewin. As one scientist at the conference observed, "I hope that this meeting will lead to a reapproachement. I hope it will set the basis for a reconstruction of ideas." A number of interesting developments have since occurred.

Punctuated Equilibrium. In 1972, Eldredge (American Museum of Natural History) and S.J. Gould (Harvard University) proposed the hypothesis of punctuated equilibrium. In explaining gaps in the fossil record, the hypothesis proclaims that the pattern of stasis and abrupt changes apparent in the record is real and not an artifact of its incompleteness. This is based on the assumption that once a species has arisen, it remains essentially unchanged for most of its history; however, when changes do occur, they do so swiftly. Also, punctuated equilibrium contrasts with other hypotheses to the effect that changes for the most part resulted from a steady accumulation of small modifications. The pattern of change accordingly would be gradual. The fossil record does not show this. The two views obviously are controversial and, as of the late twentieth century, were not resolved. As reported by Lewin (1986), several scholars have created mathematical models, which involve equations that describe the dynamics of diffusion. These models suggest that the pattern of punctuated equilibrium — stasis and rapid change — is predictable from Neo-Darwinian theory. The context of the pattern is the absence of environmental change. The models indicate that the pattern is evolution by "jerks," as it has been termed, during periods of environmental constancy.

Function and Adaptation. In evolutionary biology studies, it is frequently difficult to separate function from adaptation. Concerning neuronal circuits, for example, Dumont and Roberston (1986) observe that it may not be possible to explain many features of nervous systems in terms of adaptive significance. Rather, it may be more appropriate to consider how a neural circuit, or any other feature, is shaped during evolution. The effects of evolution can be considered to be influenced by four types of determinants: (1) adaptive influences, which are directly related to optimization of the effect of the behavior; (2) developmental constraints, which pose restrictions on the final form of the nervous system; (3) historical influences, by which the form of the present-day nervous system reflects the ancestral form; and (4) certain architectural features, which are imposed by the materials and design of the organism. Although this classification of determinants is by no means perfect, adaptation clearly does not act alone to shape a circuit during evolution. Recently, evolutionary biologists have argued for the importance of such nonadaptive processes in evolution. Gould (1982) pointed out that the brain, because of its complexity, is perhaps the most striking example of the effects of nonadaptive processes in evolution.

Morphology and Molecular Biology. The interdisciplinary nature of modern evolutionary biology was apparent at the July 1985 meeting of the Third International Congress of Systematic and Evolutionary Biology held in Brighton, England. As reported by Lewin (1985), there was a symposium on Molecules versus Morphology, which enabled the molecular biologist and the morphologist to interact. Phylogenetic reconstruction requires the search for signs of shared ancestry, specifically the identification of homologous characters that uniquely link two or more species as an evolutionarily derived group. This search, traditionally, has been for morphological structures. It now includes molecular sequences of proteins and DNA. Molecular and morphology data differ significantly as regards rate of change. If anatomical structures alter during their adaptation at least partly in response to pressures of natural selection(pressures which may differ markedly in time and magnitude), then no theoretical argument can be made for regularity of change. From the viewpoint of morphology, modification can take place in spurts, or slowly in gradual responses. In contrast, speculation and some empirical evidence indicate that molecular change may occur with considerable constancy, as guided by a so-called molecular clock. Because of this dichotomy, much additional research and indeed cooperation between the molecular biologists and morphologists will be required to bring unity out of these differing views and experiences to date.

Evolution in the Broad Sense. In a practical sense, disregarding the challenge and fascination of the theory, the primary usefulness to date of the theory of evolution has been its role as a unifying concept for the biological sciences as we know them today. This is dissimilar to the role played by the earlier (Stahl, 1600–1734) phlogiston theory (later supplanted by the laws of thermodynamics), which brought a degree of order to physics.

In essence, the various theories of cosmogony (origin of galaxies, stars, planets, etc.) furnish the prelude to the theory of evolution. In commenting on the relative chores of the cosmogonist and the evolutionary biologist, Mayr (1978) observed: "For one thing, it (biological evolution) is more complicated than cosmic evolution, and the living systems that are its products are far more complex than any nonliving system." Over the forthcoming years of continuing investigation and conceptualization, the efforts of these two fields nevertheless require coordination and tight information transfer. This is because the theory of evolution is time sensitive, even if in terms of billions of years. The best estimated age of the earth, of which only the last portion has embraced environments suitable to nurture and sustain life, must encompass all of the events described by the evolutionary biologist.

The many activities which investigators have undertaken in the past and are undertaking today to further mold and refine the theory of evolution are too numerous, complex, and detailed to report here. Several references are listed at the end of this entry for further reading.

EVOLUTION (Mathematics). See **Square and Square Root**.

EXACERBATION. When used in a medical description, exacerbation means an intensification (possibly arising from irritation, or from aggravation of underlying causes) of pain and of other symptoms of a disease or disorder that, in chronic situations, may occur intermittently. Thus, the pain and other symptoms rise above a general background of tenderness, discomfort, etc.

EXCAVATION. See **Drag Line**; and **Earthwork**.

EXCHANGE DEGENERACY. An exchange process that does not entail a change in value or configuration. For example, by the Heitler-London theory, the essential reason for the strong attraction (or repulsion), of the two H-atoms in the H_2 molecule is the exchange degeneracy, i.e., the fact that, for very large internuclear distance, by exchange of the two electrons of the two atoms, a configuration results that is indistinguishable from the original configuration. Therefore, as they approach, there arises an interaction between them, which may be treated mathematically as electron exchange.

EXCHANGE ENERGY. A specifically quantum-mechanical effect; it has no classical analog. It is due to the interaction between two systems that arises, or could arise from the continuous exchange of a particle between them.

Suppose, for example, that two electrons are in states that allow them to come close together. Then, because they are indistinguishable particles, one could not tell the difference if they exchanged states. That is, one must combine with the original description (i.e., wave-function) a function in which the electrons have actually changed places. It can easily be shown that two such combined states are possible — the symmetric and antisymmetric combinations — and that in each of these the energy is significantly different from that of the original state. Exchange energy is the origin of covalent bonding, of ferromagnetism and antiferromagnetism, probably of nuclear forces (where exchange energy could arise by exchange of π-mesons nucleons, giving rise to an effective potential which involves an operator which exchanges the spins, isotopic spins and/or positions of the particles), and of numerous other physical phenomena.

EXCHANGE FORCES. Nonclassical, quantum mechanical forces that arise from the phenomena of exchange and that account for the exchange energy. The binding of a hydrogen molecule and the covalent bonding in molecules can be looked upon loosely as due to the exchange of electrons among the atoms. The Coulomb force between charged particles can be looked upon (in quantum electrodynamics) as due to the exchange of photons. The nuclear force between nucleons can be looked upon as due to the exchange of charged or neutral π-mesons.

EXCHANGE (Particle). 1. A quantum mechanical concept based on the idea of identical particles, which are particles having the same intrinsic properties, such as rest mass, spin and charge. For example, suppose that two electrons are in states that allow them to come close together. Then, because they are indistinguishable particles, one could not tell the difference if they exchanged states. Thus the wave function of the system must be such that an exchange of the electrons leaves the magnitude of the wave function unchanged, except possibly for sign. That is, the wave function must be either symmetric or antisymmetric to an exchange of the two particles. Particles whose total wave function (including both space and spin coordinates) is symmetric under an exchange operator obey the Bose-Einstein statistics. Particles whose total wave function is antisymmetric obey the Fermi-Dirac statistics.

2. Exchange is also used more specifically as the exchange of one particle between two others, as in the exchange of the single electron between the two identical protons in the hydrogen molecular ion, or the exchange of a meson between two nucleons.

Some concepts have been altered during recent years. See also **Particles (Subatomic)**.

EXCITATION. This term has three common uses in physics and engineering: 1. Addition of energy to a system, whereby it is transferred from its ground state to a state of higher energy, called an excited state.

2. The field excitation of dynamo machines, meaning the current or voltage of the field circuit.

3. In vacuum-tube and transistor circuits, the input signal of any stage is commonly called the excitation. Thus in a radio receiver, the signal picked up by the antenna supplies the excitation for the first state, the output of the first supplies the excitation for the next, and so on.

EXCITATION CURVE. In nuclear physics, a graphical relationship between the energy of the incident particles or photons, and the relative yield of a specified nuclear reaction.

EXCITED STATE. A higher than normal energy level of the electrons of an atom, radical, or molecule, typically resulting from absorption of photons (quanta) from a radiation source (arc, flame, spark, etc.) in any wavelength of the electromagnetic spectrum, X-ray, UV, visible, infrared, microwave, and radio frequencies are used for excitation in various types of spectroscopy. When the energizing source is removed or discontinued, the atom or molecule returns to its normal or stable state either by emitting the absorbed photons or by transferring the energy to other atoms or molecules. The emission by the atom or molecule yields line or band spectra characteristic of its structure, thus permitting identification. Photochemical reactions are induced by excited chemical entities, which are also responsible for the phenomena of luminescence (phosphorescence and fluorescence). See also **Fluorescence**; and **Luminescence**.

EXCITER. This term has four common uses in engineering: 1. In antenna terminology, the portion of a transmitting array of the type that includes a reflector directly connected with the source of power.

2. In transmitters, the oscillator that supplies the carrier or subcarrier frequency voltage to drive the stages that ultimately lead to the final power output stage. In FM systems this unit includes all the frequency generating, modulating and frequency multiplying circuits of the transmitter.

3. In photoelectric reproduction of film, the lamp that supplies a light source of constant amplitude.

4. A generator used to supply the field currents of a larger direct current generator or of an alternator.

EXCITING CURRENT (Transformer). This is the current which supplies the core losses and magnetizing current for a transformer. When the transformer is supplying a load this excitation current is one component of the total input, the other being the component which balances the load current. The current establishes the magnetic field in the core, furnishing energy for the no-load power losses in the core. It is also called *magnetizing current*.

EXCLUSIVE OR CIRCUIT. A logical element that has the properties that if either of the inputs is a binary 1, then the output is a binary 1. If both the inputs are a binary 1 or 0, the output is a binary 0. In terms of Boolean algebra, this function is represented as $F = AB' + BA'$, where the prime denotes the **NOT** function. With reference to the transistor exclusive **OR** circuit shown in the accompanying diagram, the output is positive when either transistor is in saturation. When input A is positive and B is negative, transistor T_2 is in saturation. When B is positive and A is negative, transistor T_1 is in saturation. When A and B are either both positive or both negative, then both transistors are cut off and the output F is negative.

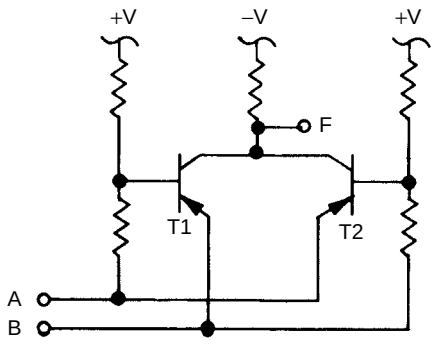

Fig. 1. Exclusive OR circuit.

Although shown as discrete devices in Fig. 1, fabrication using large-scale integrated circuit technology may utilize other circuit and device configurations.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

EXCRETION. The removal of the waste products resulting from the chemical transformation of materials in the body.

The oxidation of materials derived from foods for the release of energy may produce carbon dioxide and water, whether the compound oxidized is a protein, a carbohydrate, or a fat. Since proteins contain nitrogen and other elements in addition to carbon, hydrogen, and oxygen, they also give rise to more complex waste products. The chief nitrogenous wastes of animals are urea and uric acid. The elimination of all of these compounds and other substances of like derivation is excretion.

Many small animals, including both protozoans (*Protozoa*) and more complex forms, apparently discharge these wastes from the surface of the body generally, while in others a special excretory system occurs. Even in those forms that have a complex excretory system, any moist surface directly or indirectly exposed to the medium surrounding the animal is favorable for the diffusion of materials into or out of the body, and so may carry on excretion. The wastes passed out in this manner are largely carbon dioxide and water, although the discharge of water may also take out dissolved solids. Thus, the lungs of a terrestrial vertebrate eliminate carbon dioxide and the sweat glands of the skin of some animals discharge water with other materials, including nitrogenous wastes, in solution. By far the greater part of the complex wastes is eliminated by the excretory system.

In complex animals, other organs than those directly involved in the elimination of wastes may play an important intermediary role. The circulatory system of the vertebrate, for example, transports all wastes from the tissues where they are formed to organs that act upon them and finally to the centers which remove them from the body. The liver removes some substances, including complex organic compounds resulting from the destruction of old red blood cells, and discharges them in the bile by way of the intestine. It also transforms ammonia and amino acids, resulting from the oxidation of proteins, into urea, which is returned to the blood to be removed by the kidneys.

See also **Urine**.

EXCRETORY SYSTEM. An organic system whose principal or only function is the removal of complex wastes from the animal body. The excretory system of humans is discussed under **Kidney and Urinary Tract**.

Some animals lack an organized excretory system, discharging wastes from the surface of the body generally, but others, even among the one-celled animals, have special excretory structures. The contractile vacuoles of protozoa are supposed to carry out this function.

In the flatworms a special excretory system based on the flame cell appears. Flame cells are large and hollow, with a group of cilia projecting into the cavity whose movement drives out the liquid discharged by the cell. The cavity of each flame cell joins a small duct and these ducts converge to form larger ducts, which ultimately open at the surface of the body. Flame cells emptying by ducts into a vesicle connected with the caudal end of the alimentary tract also occur in rotifers.

Roundworms have two slender excretory canals along the sides of the body which unite to empty by a single pore near the anterior end.

In the segmented worms, the body cavity becomes involved in excretion. Two forms of tubes, the coelomoducts and nephridia, open from the coelom to the exterior in these worms. These organs are segmentally arranged ciliated tubes with a funnel-shaped inner end and a minute opening externally. They are variously associated in the excretory organs of different species and in some do not open into the coelom but are provided with cells much like flame cells which are called solenocytes.

Arthropods of different classes have special excretory structures, including the coxal glands of scorpions, said to be derived from coelomoducts, and the Malpighian tubules of insects. The latter are slender tubules opening into the alimentary tract at the caudal end of the stomach and blind at their other end.

The occurrence of solenocytes in the lancelets of the phylum *Chordata* is unusual in this phylum, since in the true vertebrates a pair of kidneys is the chief excretory structure. They are developed from intermediate mesoderm. The excretory unit in these organs is a minute tubule, which has in its primitive form a ciliated funnel leading from the coelom. At their lateral ends the series of tubules unite to form a duct which grows back to empty into the cloaca. The tubule is associated with a knot of blood vessels near the coelomic opening (the nephrostome). In a more advanced stage of development excretory tubules lack the nephrostome and have the

wall expanded to form Bowman's capsule, embracing the knot of blood vessels which is called a glomerulus. This unit, known as a renal corpuscle, is found in the kidneys of most vertebrates. The tubule leading from it is also specialized for the removal of wastes from the blood.

Three pairs of kidneys are found in different vertebrates and appear in succession in the embryos of the higher classes, the reptiles, birds, and mammals. In cyclostomes and embryos of fishes and amphibians the kidney are pronephroi, lying well forward in the body and made up of tubules of the primitive type. The pronephroi are vestigial in embryonic reptiles, birds and mammals. Functional kidneys in these embryos and in the adults of cyclostomes, fishes and amphibia are the mesonephroi, lying behind the pronephroi and made up of closed tubules. As they develop, these tubules connect with the duct formed by the pronephroi; this duct is then called the mesonephric or Wolffian duct. In adult reptiles, birds and mammals the mesonephroi are replaced by the metanephroi, lying still farther back. Their tubules develop in a mass of tissue surrounding a blind diverticulum of the mesonephric duct.

The connection of the excretory ducts with the cloaca persists in many vertebrates but, in the true mammals, this passage splits to form a dorsal rectum and a ventral urogenital sinus which receives the Wolffian duct. An expanded reservoir, the urinary bladder, developed ventrally in connection with the cloaca, ultimately receives the ducts of the metanephroi, while the remainder of the mesonephric duct persists in the male as the main duct of the testis. The relations of all these parts differ greatly in animals of different groups. In all animals with metanephroi the ducts leading from the kidneys are called the ureters and a separate duct from the urinary bladder to the exterior is the urethra.

EXHALATION. 1. In soil science, the process by which radioactive gases escape from the surface layers of soil or loose rock where they are formed by decay of radioactive salts. The exhalation of radioactive gases, notably radon and thoron, increases with soil temperature and so normally exhibits a single daily maximum around midday. Decreases of atmospheric pressure normally increase the exhalation, and freezing of the surface soil layers usually greatly reduces it.

2. The streaming forth of volcanic gases; also the escape of gases from a magnetic field.

EXIT SLIT. A narrow opening in an opaque screen; when a spectrum is produced upon the screen, by a spectrometer, the slit passes only a small portion of the spectrum, which is then focused onto a detector.

EXOGENETIC. A general term designating all surface, or near-surface, geologic processes such as: erosion, deposition, and secondary enrichment of ore bodies. The term is not particularly applicable to volcanism.

EXOSMOSIS. An osmotic process by which a diffusible substance passes from the inner or closed, to the outer parts of a system, as in the loss of substances from a portion of a plant root to water in the surrounding soil.

EXOSPHERE. The outermost, or topmost, portion of the atmosphere. Its lower boundary is the critical level of escape, variously estimated at 500 to 1000 kilometers above the earth's surface. Also called *region of escape*. In the exosphere, the air density is so low that the mean free path of individual particles depends upon their direction with respect to the local vertical, being greatest for upward moving particles. It is only from the exosphere that atmospheric gases can, to any appreciable extent, escape into outer space.

EXOTROPIA. Exotropia is one of the most common forms of strabismus, a condition that refers to any misalignment of the eyes. In the case of exotropia, one eye deviates outward (away from the nose) while the other fixates normally. Esotropia is the condition where one eye deviates inward (toward the nose). Esotropia is the most common type of strabismus in infants, while exotropia often begins between the ages of 2 and 4. About 4 percent of all children in the United States have some form of strabismus. It occurs equally in males and females and is sometimes hereditary. The condition can also develop later in life.

The brain's ability to see three-dimensional objects depends on proper alignment of the eyes. When both eyes are properly aligned and aimed at the same target, the visual portion of the brain fuses the forms into a single image. When one eye turns inward, outward, upward, or downward, two different pictures are sent to the brain. This causes loss of depth perception and binocular vision.

The causes of exotropia are not fully understood. There are six muscles that control eye movement, four that move it up and down and two that move it side to side. All these muscles must be coordinated and working properly in order for the brain to see a single image. When one or more of these muscles doesn't work properly, some form of strabismus may occur. Strabismus is more common in children with disorders that affect the brain such as cerebral palsy, Down syndrome, hydrocephalus, and brain tumors.

The earliest sign of exotropia is usually a noticeable outward deviation of the eye. This symptom may at first be intermittent, occurring when a child is daydreaming, not feeling well, or tired. The deviation may also be more noticeable when the child looks at something in the distance. Squinting or frequent rubbing of the eyes is also common with exotropia. Your child probably will not mention seeing double, i.e., double vision. However, he or she may close one eye to compensate for the problem.

Generally, exotropia progresses in frequency and duration. As the disorder progresses, the eyes will start to turn out when looking at close objects as well as those in the distance. If left untreated, the eye may turn out continually, causing a loss of binocular vision. In young children with any form of strabismus, the brain may learn to ignore the misaligned eye's image and see only the image from the best-seeing eye. This is called amblyopia, or lazy eye, and results in a loss of depth perception. In adults who develop strabismus, double vision sometimes occurs because the brain has already been trained to receive images from both eyes and cannot ignore the image from the turned eye.

A comprehensive eye examination including an ocular motility (eye movement) evaluation and an evaluation of the internal ocular structures will allow an eye doctor to accurately diagnose the exotropia. Although glasses and/or patching therapy, exercises, or prisms may reduce or help control the outward-turning eye in some children, surgery is often required.

The most reliable treatment for exotropia is usually eye muscle surgery, but this is often preceded by eye patching and/or eyeglass therapy, especially if amblyopia (lazy eye) is present. This therapy is designed to maximize the existing vision in the weaker eye. In some children, this therapy may eliminate the need for surgery. There is a rare form of exotropia known as "convergence insufficiency" that responds well to therapy. This disorder is characterized by an inability of the eyes to work together when used for near viewing, such as reading. Instead of the eyes focusing together on the near object, one deviates outward.

Surgery is usually recommended if the exotropia is present for more than half of each day or if the frequency is increasing over time. Surgery is also indicated if a child has significant exotropia when reading or viewing near objects or if there is evidence that the eyes are losing their ability to work as a single unit (binocular vision). If none of these criteria are met, surgery may be postponed pending simple observation with or without some form of eyeglass and/or patching therapy. In very mild cases, there is a small chance that the exotropia will diminish with time.

The surgical procedure for the correction of exotropia involves making a small incision in the tissue covering the eye in order to reach the eye muscles. The appropriate muscles are then repositioned in order to allow the eye to move properly. The procedure is usually done under general anesthesia. Recovery time is rapid, and most people are able to resume normal activities within a few days. Following surgery, corrective eyeglasses may be needed and, in many cases, further surgery is required later to keep the eyes straight.

When a child requires surgery, the procedure is usually performed before the child attains school age. This is easier for the child and gives the eyes a better chance to work together. As with all surgery, there are some risks. However, strabismus surgery is usually a safe and effective treatment. See also **Amblyopia**; **Esotropia**; and **Strabismus (Cross-Eyes)**.

Vision Rx, Inc., Elmsford, NY

EXPANDER (Signal). That part of the communication circuit designed to expand the volume range back to the original value as it is normally compressed for transmission. Weak signals are attenuated and strong signals are amplified.

EXPANSION JOINT. Metals constituting pipes have the property possessed by all materials, of expanding with increase of temperature. Were they constrained to a fixed length, a reaction equivalent to the force required to compress the pipe through a deformation equal to the prevented expansion would be set up. For all but very short steam lines this force is too large to incorporate in the piping system. The same force would be present, theoretically, in the short line, but the supports would have enough elasticity to take the small expansion. In long lines the expansion is permitted by the use of suitable joints and bends. See Fig. 1.

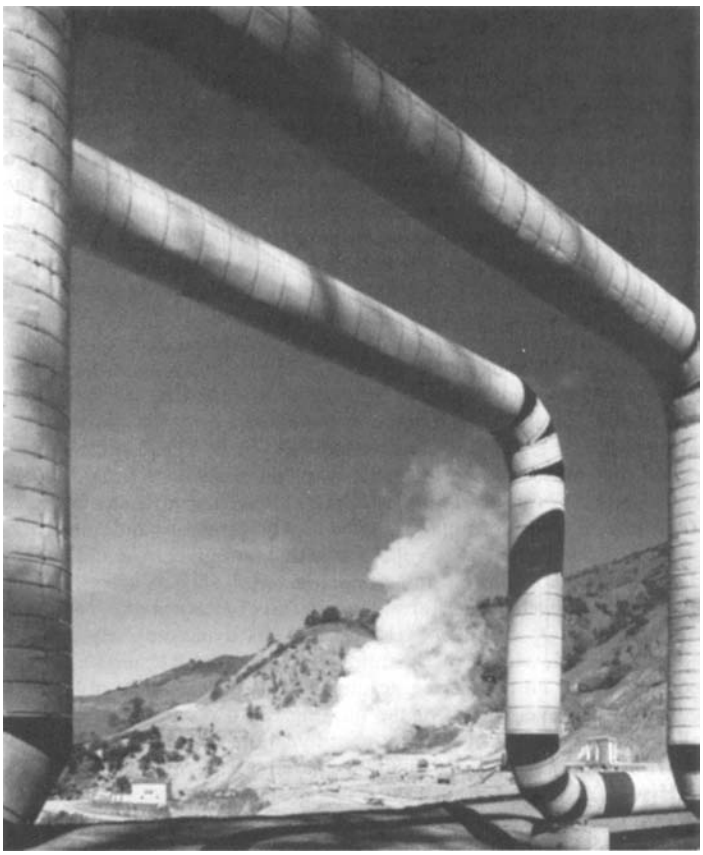

Fig. 1. Expansion loops that carry geothermal steam from wells to electric generating station. Located at *The Geysers*, Sonoma County, California. (*Pacific Gas and Electric Co.*)

Both packed and packless expansion joints are used for saturated steam at pressures up to 250 psi (17 atmospheres). High temperature has a deteriorating effect on packing; however, packed joints have been designed for high temperature by protecting the packing by air-cooled sleeves. Expansion joints take up expansion at one point by allowing relative motion of the two sections of pipe connected by the joint. Usually one pipe end is anchored by a rigid connection to the body of the joint but occasionally the double slip joint in which both pipe ends are free to move in the joint is used.

When expansion is to be taken by the flexibility of the pipe itself various forms of pipe bends are used. This way of caring for expansion is free of the temperature-pressure limitations of the expansion joints and also of any maintenance work such as the repacking of joints. Consequently, it has been the standard for boiler and turbine leads and for long runs of high-pressure piping of all sorts. Its principal drawbacks are the added friction losses, the expense of fabrication (most bends are special jobs), and the space required.

EXPANSION TURBINE. See **Gas and Expansion Turbines**.

EXPECTED VALUE. The expected value of a function of variate values is its mean value in repeated sampling. If $F(x)$ is the cumulative distribution function of a variate x, the expected value of a quantity t depending on x is

$$\int_{-\infty}^{\infty} t\, dF(x)$$

It is in fact the average or mean value of t over the distribution of x.

EXPLOSIVE. In the conventional sense, a solid, gas, or liquid material which, when triggered, will release a great amount of heat and pressure by way of a very rapid, self-sustaining exothermic decomposition. This entry does not describe nuclear explosives.

There are two principal classes of explosives: (1) *deflagrating explosives*, whose burning processes are rather slow — with progressive reaction rates and buildup of pressure that create a heaving action; and (2) *detonating explosives*, which are characterized by very rapid chemical reactions, thus causing tremendously high pressure and brisance (shattering action). In the latter, detonation waves may obtain a velocity in excess of 20,000 feet per second. The decomposition of cellulose nitrate used in propellants typifies the deflagrating type: $C_{24}H_{30}N_{10}O_{40} \rightarrow 5N_2 + 10H_2 + 5H_2O + 11CO_2 + 13CO$. The decomposition of nitroglycerine typifies the detonating type: $4C_3H_5(ONO_2)_3 \rightarrow 12CO_2 + 10H_2O + 6N_2 + O_2$.

Black powder, using KNO_3 or $NaNO_3$, charcoal and sulfur was probably the first explosive developed and is attributed either to Chinese or Egyptian ingenuity. The time of first use occurred before the birth of Christ. This is a deflagrating explosive and was adapted for blasting purposes as early as the 1600s.

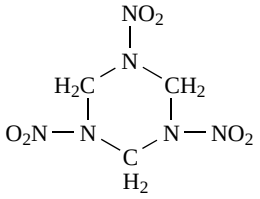
Black powder (gunpowder) consists of an intimate mixture of finely divided solids, 75% potassium nitrate, 15% carbon, 10% sulfur. Powders for sporting guns contain a slightly larger percentage of potassium nitrate (75 to 78%, smaller percentage of carbon (15 to 12%), and a variation in sulfur from 9 to 12%. Mining or blasting powders, where large volumes of gas are desired, may have 14 to 21% carbon and 13 to 18% sulfur. When ignited, potassium nitrate supplies oxygen for the combustion of explosives, of carbon to carbon dioxide and of sulfur to sulfur dioxide. One gram of powder yields 250 to 300 milliliters of gas measured at 0 °C and 760 mm pressure. The heat evolved per gram is 500 to 700 calories, and the temperature of the explosion is estimated at 2,700 °C.

Among the earliest high explosives were *mercury fulminate*, $HgC_2N_2O_2$, developed late in the seventeenth century, and *nitrostarch*, $C_{12}H_5(ONO_2)_{30}$, discovered by Braconnot in 1832 and still used as a sensitizing ingredient in modern commercial explosives. *Nitrocotton* was produced in 1838 by Dumas and Pelouse by treating cotton and paper with nitric acid, in the same way that Braconnot treated starch with HNO_3. *Nitroglycerin*, $C_3H_5(ONO_2)_3$, was first made by Sobrero. Early nitroglycerin formulations were highly dangerous and caused numerous accidents. In 1867, Nobel found that nitroglycerin could be rendered safe by absorbing it in a porous material, such as kieselguhr, or diatomaceous earth. After formulation of this first *dynamite*, Nobel introduced $NaNO_3$ and later NH_4NO_3 into his dynamite formulations. Nobel, in 1875, while experimenting with cellulose tetranitrate, mixed collodion with nitroglycerine, resulting in the development of blasting gelatin. The development of the blasting cap used with a safety fuse allowed for safe, positive initiation of dynamite.

Wilbrand, in 1863, first prepared *trinitrotoluene* (TNT), $C_6H_2(CH_3)(NO_2)_3$. The material was not manufactured in production quantities until about 1900. The German military recognized the advantages of TNT as a replacement for *picric acid*, which they had used earlier. TNT was used extensively during World War I and became a standard military explosive.

Tollens, in 1891, prepared *pentaerythritol tetranitrate* (PETN), $C(CH_2NO_3)_4$, but this compound was not commercially available until after World War I. Commercial production had to await a lowering in the cost of formaldehyde and acetaldehyde used in its production.

Henning, in 1899, discovered *cyclotrimethylenetrinitramine* (cyclonite-RDX), but its potential was not realized until about 1920. RDX was used extensively during World War II as a component of numerous cyclotols, plastic explosives, and bursting charges.



(RDX)

Although ammonium nitrate, NH_4NO_3, was known to have explosive qualities as early as 1659, it was not used much in explosive formulations until about 1867. At that time, it was used by Nobel to replace a portion of nitroglycerin in dynamite. Because of critical toluene shortages during World War I, NH_4NO_3 was used as a way of conserving TNT. Mixtures containing 80% NH_4NO_3 and 20% TNT; or 50–50 mixes were used. These became known as 80:20 or 50:50 *amatols* and were used as military explosives for shells and bombs. In World War II, particularly by the Axis powers, amatols were used, again to conserve TNT. The Texas City, Texas disaster of 1947 (explosion of ship loaded with NH_4NO_3) reemphasized the potential of this substance for explosives. Later, Robert Akre used a combination of prilled NH_4NO_3 and carbon black (94:6 mix) in making an explosive for blasting in open-pit strip mines. The substance was patented under the name *Akremite*. Later experiments included mixing liquid hydrocarbons to replace the carbon black. This resulted in ANFO explosives. It was found that diesel fuel oil can be mixed with NH_4NO_3 with a consistent quality. Commencing in the late 1950s, ANFO explosives became widely accepted.

Unfortunately, the water resistance of ANFO is low and numerous experiments in attempting to dry-package it were not markedly successful. This shortcoming of ANFO led Cook, Farnum, and others to develop *slurry explosives*. These materials are comprised of: oxidizers, such as NH_4NO_3 and $NaNO_3$ fuels, such as coals, oils, aluminum, and other carbonaceous materials; sensitizers, such as TNT, nitrostarch and smokeless powder; and water — all mixed with a gelling agent to form a thick, viscous explosive having excellent water-resistant properties. These explosives are made as cartridged units or are mixed at the site in bulk and then pumped into place.

The largest consumers of commercial explosives are the mining, construction, and seismic-prospecting industries. Explosives are also used in agriculture for blasting stumps, setting posts, breaking up hardpan, clearing land, digging wells, and blasting drainage and irrigation ditches. Explosive technology also is applied by industry in the forming, cladding, bonding, hardening, and welding of metals. On a small scale, explosive-actuated devices are used in valves, switches, and relays, as well as for cutting, punching, riveting, and fastening metals.

See Fig. 1, a typical quarry blast using a millisecond delay electric blasting cap.

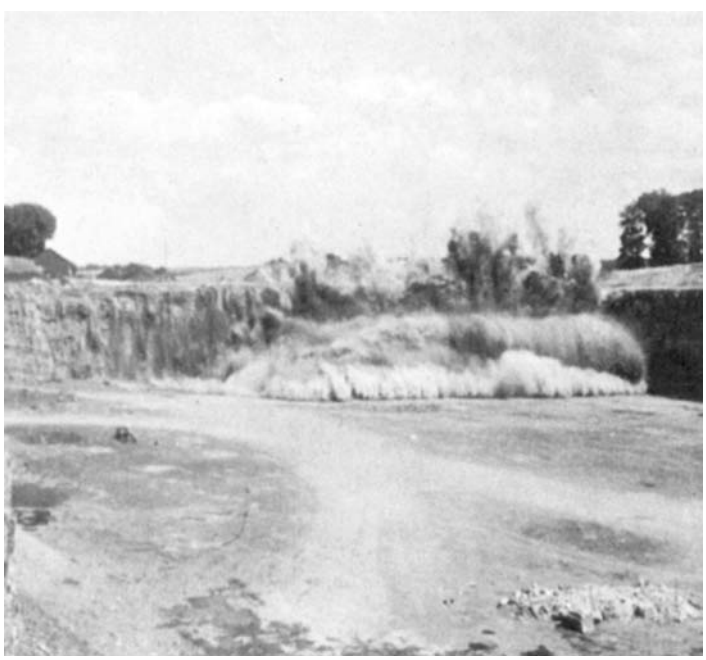


Fig. 1. Quarry blast utilizing high explosives initiated with electrical delay devices (millisecond delay electric blasting caps).

EXPONENT. Also called index, it is the power to which an algebraic expression is raised. It can be positive or negative, integral or fractional. If m and n are positive integers and a, b are numbers or functions, the following are some of the properties of the exponent:

$$a^m \times a^n = a^{(m+n)}$$
$$a^m / a^n = a^{(m-n)}$$
$$a^{-m} = 1/a^m$$
$$(a^m)^n = a^{mn}$$
$$a^{1/m} = \sqrt[m]{a}$$
$$\sqrt[m]{\sqrt[n]{a}} = \sqrt[mn]{a}$$
$$a^{m/n} = \sqrt[n]{a^m}$$
$$(ab)^m = a^m b^m$$
$$(a/b)^m = a^m / b^m$$
$$\sqrt[m]{ab} = \sqrt[m]{a}\sqrt[m]{b}$$
$$\sqrt[m]{a/b} = \sqrt[m]{a} / \sqrt[m]{b}$$

An exponential function is transcendental, an example being $y = ab^x$, where a, b are constants and x is the independent variable. If $a = 1$, it is the inverse of the logarithmic function. Some properties of its curve are: (a) it is not symmetric to either the X- or Y-axis or to the origin; (b) it intersects the Y-axis at $y = 1$, but its asymptote is the X-axis; (c) no finite value of x makes y infinite. If $b < 1$, $y \to 0$ as $x \to \infty$ and decreases continuously as x increases; if $b > 1$, $y \to 0$ as $x \to -\infty$ and increases continuously with x; if $b = 1$, the curve becomes the straight line $y = 1$.

The most convenient value to choose for b is the transcendental number e. Its curve is similar to the more general one described for the number b but its slope is different.

An exponential equation contains one or more exponential functions. It can often be solved by taking the logarithm of both sides and solving the resulting algebraic equation.

Euler's theorem on the exponential function is $\cos x \pm i \sin x = e^{\pm ix}$.

EXPONENTIAL DISTRIBUTION. A distribution of the form

$$dF = \frac{1}{\sigma} \exp\left(-\frac{x-m}{\sigma}\right) dx, \quad m \le x \le \infty$$

The parameter σ is the standard deviation of the distribution and is equal to the distance of the mean from the start.

EXPONENTIAL SMOOTHING. A method used in forecasting a variable from values of that variable occurring at previous points of time. It relies on a weighted average of those previous values, and on the reasonable assumption that, because values in the more remote past are of less influence on the present, the weights attached to the values diminish for the less recent values. Such a forecast at time t of a variable u_t, for example, might be

$$u_t(\text{forecast}) = (1 - \beta) \sum_{i=1}^{\infty} \beta^{j-1} u_{t-j}$$

The coefficients diminish according to the exponent of the coefficient β; hence the name of the procedure. More elaborate forms of the same basic method are also known as exponential smoothing.

EXPRESSION (Mechanical). The separation of liquids from solids by compressing (squeezing) certain liquid-containing substances, such as separating oils from vegetable seeds and nuts. Equipment is designed to permit the liquids to be removed while retaining the solids between the compressing surfaces. Expression equipment takes several configurations. In the *plate press*, the material to be expressed, such as fruit or seeds, is wrapped in special plate cloths. These then are placed between a series of hydraulically operated plates, which act upon the materials much as a vise. The pressure usually is applied in stages, with the maximum pressure applied close to the end of a 20-to-45-minute total cycle. The *box press* is similar with the exception that shallow boxes enclose the pressed cake on two sides, thus simplifying the folding of the press cloths. The *cage press* consists of a cylinder, finely perforated, with a hydraulically operated ram. Essentially, the material to be expressed is squeezed at one end of the cylinder by the ram. The expressed oil flows through the perforations. Several pressings (strokes of the piston or platen) are usually required. In the *pot press*, the cage is replaced by a series of short, superimposed steam-heated pots. Usually a series of pots is used in each press, the bottom of each pot serving as the ram for the pot below. The *curb press* also is similar to the cage press, but operates at lower pressures with fewer drainage channels. The screw press consists of a continuous screw or worm that rotates within a cylinder housing lined with perforated plates. A powerful squeezing action results from the taper of the screw. In the *V-disk press*, two conical disks face each other in a suitable casing. As the disks rotate, they converge from a point of maximum gap (point of feed) to a point of minimum gap (point of discharge). Designs with hydraulic systems permit the disks to oscillate during operation to maintain constant pressure. The *roll press* operates on the principle of the old-fashioned clothes wringer, with two to three rollers through which the feed is passed, the expressed liquids collecting in a trough below.

Operating characteristics of the various forms of expression equipment are summarized in Table 1.

TABLE 1. EXPRESSION EQUIPMENT

Type of Press and Applications	Oil Fat, Liquids in Feed	Cake Discharge
Plate. Vegetable seeds, nuts, olives, fruit, notably flaxseed	30–35%	5–10% oil
Box. Vegetable seeds, nuts, notably peanuts and cottonseed	30–35%	5–10% oil
Cage. Most oil seeds and nuts. Almost any oil material, notably copra and castor beans	35–50%	5–10% oil
Pot. Fats, such as cocoa butter not liquid at room temperature	30–50%	6–10% fat
Screw (Low-pressure type). Wastewater slurries, wood and wood pulp; food and Beverage products	90–97%	25–50% solid
Screw (High-pressure type). Vegetable seeds and nuts; rubber; rendered materials	30–35%	3–5% oil
V-disk. High-polymer resins, spent grains, wood and pulp Products, food and starch Products, wastewater slurry	85–97%	25–55% solid
Roll. Alkali cellulose, sugar cane, wood and pulp products	92–98%	30–55% solid

EXSOLUTION. See **Mineralogy**.

EXTENSOMETER. A device for determining small linear dimensional changes caused by the application of a stress. Thus, an extensometer is used to determine the changes in length of the gage section of a tensile specimen during a tensile test.

EXTINCTION COEFFICIENT. 1. A measure of the space rate of diminution, or extinction, of any transmitted light; thus, it is the attenuation coefficient applied to visible radiation. The extinction coefficient is identified in a form of Bouguer's law (or Beer's law):

$$dl = -\sigma I \, dx$$

or

$$I = I_0 e^{-\sigma x}$$

where I is the illuminance (luminous flux density) at the selected point in space, I_0 is the illuminance at the light source, and x is the distance from the source.

When so used, the extinction coefficient equals the sum of the medium's absorption coefficient and scattering coefficient, each computed as a weighted average over all wavelengths in the visible spectrum. So long as scattering effects are primary, as in the lower atmosphere, the value of the extinction coefficient is a function of the particle size of atmospheric suspensoids. It varies in order of magnitude from 10 km^{-1} with very low visibility to 0.01 km^{-1} in very clear air.

The extinction coefficient is related to the transmission coefficient τ as follows:

$$\tau = e^{-\sigma}$$

2. In oceanography, the extinction coefficient is a measure of the attenuation of downward-directed radiation in the sea. The coefficient K is defined by

$$K = 2.303 \log \frac{I_{\lambda 1}}{I_{\lambda 2}}$$

where $I_{\lambda 1}$ is the intensity of radiation of a given wavelength λ on a horizontal surface and $I_{\lambda 2}$ is the intensity on a horizontal surface 1 meter deeper. K varies with wavelength, with the nature of the scattering particles, and with the presence of dissolved colored substances.

EXTRACAPSULAR CATARACT EXTRACTION (ECCE). A method of a cataract surgery that involves removing the eye's natural lens while leaving in place the back of the capsule that holds the lens in place. The procedure requires a much smaller incision than the older procedure called *intracapsular cataract extraction* in which the lens and the entire capsule were removed. A modified form of *extracapsular cataract extraction* is called *phacoemulsification* and uses an even smaller incision, requiring no sutures at all.

To understand the significance of ECCE, it is important to understand what a cataract is and how it interferes with vision. The eye works like a camera with two lenses. The first lens is the cornea, a clear membrane that covers the front of the eye. The second lens is the eye's natural crystalline lens, which is held in place by a capsule located behind the pupil. The cornea is responsible for about 70% of the eye's focusing power, while the natural lens fine-tunes the image.

When the natural lens becomes cloudy, usually because of the aging process, it keeps light rays from passing through or diffuses the light in such a way that vision becomes fuzzy or hazy. This cloudy lens is called a cataract. The object of modern cataract surgery is to remove this hazy lens and to replace it with a tiny plastic prescription lens that is permanently implanted in the eye.

In *extracapsular cataract extraction*, the surgeon makes a tiny incision in the white of the eye near the outer edge of the cornea. The size of this opening depends on whether the nucleus of the lens is to be removed all in once piece or whether it will be dissolved into tiny pieces and then vacuumed out (phacoemulsification). The surgeon then enters the eye through this incision and carefully opens the front of the capsule that holds the lens in place. After the nucleus or hard center of the lens is removed, the soft lens cortex is suctioned out, leaving the back of the capsule in place in order to strengthen and support placement of the intraocular lens.

After the natural lens is removed, a prescription intraocular lens implant is placed behind the iris, where the eye's natural lens used to be. The incision through which the lens was removed requires sutures if the lens was removed in one piece. If the phacoemulsification technique is employed, sutures are usually not required to close the incision. Although glasses may still be necessary for some tasks after cataract surgery, most patients are happy with the results. See also **Cataract**; **Intracapsular Cataract Extraction (ICCE)**; and **Vision and the Eye**.

Vision Rx, Inc., Elmsford, NY

EXTRACTION (LIQUID-LIQUID). Liquid–liquid extraction, often loosely referred to as solvent extraction, was carried out as early as Roman times when silver and gold were extracted from molten copper using lead as a solvent. The first significant industrial application of solvent extraction was in the petrochemical industry. See also **Petroleum**. This was followed by applications for the recovery of and the purification of penicillin (see **Antibiotics**, **β-lactams**), and since 1945 in the nuclear industry in the refining of uranium, plutonium, and other radioisotopes. Since 1960, solvent extraction has been applied on a large scale in the refining of other nonferrous metals, particularly copper. Most recently it has gained increasing importance as a separation technique in biotechnology. See also **Extraction(Liquid-Solid)**.

The physical process of liquid–liquid extraction separates a dissolved component from its solvent by transfer to a second solvent, immiscible with the first but having a higher affinity for the transferred component. The latter is sometimes called the consolute component. Liquid–liquid extraction can purify a consolute component with respect to dissolved components which are not soluble in the second solvent, and often the extract solution contains a higher concentration of the consolute component than the initial solution. In the process of fractional extraction, two or more consolute components can be extracted and also separated if these have different distribution ratios between the two solvents.

The principle of liquid–liquid extraction, and some of the special terminology, are illustrated in Figure 1 which shows a single contacting stage. If equilibrium is fully established after contact, the stage is defined as an ideal or theoretical stage. The two resulting liquid phases are the raffinate from which most of solute C has been removed, and the extract, consisting mainly of solvent B and C.

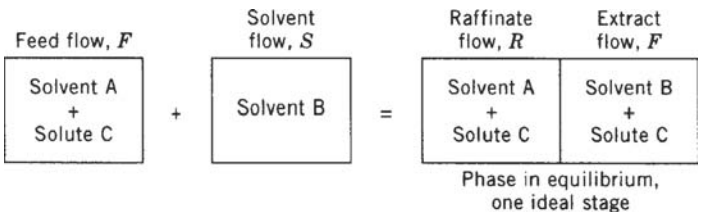

Fig. 1. Single contacting stage

In the simplest case, the feed solution consists of a solvent A containing a consolute component C, which is brought into contact with a second solvent B. For efficient contact there must be a large interfacial area across which component C can transfer until equilibrium is reached or closely approached. On the laboratory scale this can be achieved in a few minutes simply by hand agitation of the two liquid phases in a stoppered flask or separatory funnel. Under continuous flow conditions it is usually necessary to use mechanical agitation to promote coalescence of the phases. After sufficient time and agitation, the system approaches equilibrium which can be expressed in terms of the extraction factor ε for component C:

$$\varepsilon = \frac{\text{quantity of C in B-rich phase}}{\text{quantity of C in A-rich phase}} = m\frac{B}{A} \quad (1)$$

where B and A refer to the quantities of the two solvents and m is the distribution coefficient.

The component C in the separated extract from the stage contact shown in Figure 1 may be separated from the solvent B by distillation, evaporation, or other means, allowing solvent B to be reused for further extraction. Alternatively, the extract can be subjected to back-extraction (stripping) with solvent A under different conditions, eg, a different temperature; again, the stripped solvent B can be reused for further extraction. Solvent recovery is an important factor in the economics of industrial extraction processes.

Whereas Figure 1 assumes a physical extraction based on different solubilities as expressed by the distribution coefficient, many extractions depend on chemical changes. In such cases the component C in the feed solvent may not itself have any solubility in the extracting solvent B, but can be made to react with an extractant to produce a compound or species which is soluble in B. Many metals can be extracted from aqueous solutions of their salts into organic carrier solvents by using organic extractants which can form organometallic compounds or complexes. Stripping of the metals from the organic to an aqueous phase can be effected by changing a chemical condition such as pH.

Principles

In order for two separate liquid phases to exist in equilibrium, there must be a considerable degree of thermodynamically nonideal behavior. If the Gibbs free energy, G, of a mixture of two solutions exceeds the energies of the initial solutions, mixing does not occur and the system remains in two phases. For the binary system containing only components A and B, the condition for the formation of two phases is

$$\frac{d^2G}{dx_A^2}\rangle \quad (2)$$

The selection of solvents for a given separation depends largely 0 on equilibrium considerations. Other important factors include cost, ease of solvent recovery by distillation or other means, safety and environmental impact, and physical properties which must permit easy phase dispersion and separation. Solvent selection is therefore a broad-based exercise which is hard to quantify. However a useful quantitative approach has been proposed for comparing simplified equilibrium estimations on the basis of regular solution theory.

In many cases, mass transfer between two liquid phases is accompanied by a chemical change. The transferring species can dissociate or polymerize depending on the nature of the solvent, or a reaction may occur between the transferring species and an extractant present in one phase.

In addition to the liquid–liquid reaction processes, there are many cases in both analytical and industrial chemistry where the main objective of separation is achieved by extraction using a chemical extractant. The technique of dissociation extraction is very valuable for separating mixtures of weakly acidic or basic organic compounds such as 2,4-dichlorophenol [CAS: 120-83-2], $C_6H_4C_{l2}O$, and 2,5-dichlorophenol [CAS: 583-78-8], which are difficult to separate by other means. The technique involves the use of a controlled amount of a strong base or acid in the aqueous phase, so that the overall distribution of each species is affected by its dissociation constant as well as the distribution constant of the undissociated form. Dissociation extraction has been applied extensively to mixtures of closely similar phenols, amines, and organic acids.

In hydrometallurgical separations, a metal ion in aqueous solution can be selectively converted to an organometallic compound or complex which is soluble in an organic carrier solvent. The metal extractants may be classified as: (1) acid and chelating acid extractants, (2) anion exchangers, and (3) solvating extractants. Acid extractants typically contain one or more long hydrocarbon chains, an example being di(2-ethyl-hexyl)phosphoric acid [CAS: 298-07-7], $[C_4H_9CH(C_2H_5)CH_2]_2HPO_4$.

Chelating extractants owe effectiveness to the attraction of adjacent groups on the molecule for the metal. Compounds containing long hydrocarbon chains and the hydroxyoxime group, or those based on

8-quinolinol [CAS: 148-24-3], C_9H_6NOH, form the basis of various commercial formulations. Anionic extractants are commonly based on high molecular weight amines. Solvating extractants contain one or more electron donor atoms, usually oxygen, which can supplant or partially supplant the water which is attached to the metal ions. Perhaps the best known example of such an extractant is tri-(*n*-butyl) phosphate) [CAS: 126-73-8] (TBP), $C_{12}H_{27}O_4P$, which forms the basis of the PUREX process.

Whereas equilibrium relationships are important in determining the ultimate degree of extraction attainable, in practice the rate of extraction is of equal importance. Equilibrium is approached asymptotically with increasing contact time in a batch extraction. In continuous extractors the approach to equilibrium is determined primarily by the residence time, defined as the volume of the phase contact region divided by the volume flow rate of the phases.

The rate of mass transfer depends on the interfacial contact area and on the rate of mass transfer per unit interfacial area, i.e., the mass flux. The mass flux very close to the liquid–liquid interface is determined by molecular diffusion in accordance with Fick's first law:

$$N = -D\frac{\partial c}{\partial z} \tag{3}$$

where N refers to the flux in the z direction, c is the concentration of the consolute component, and D is its molecular diffusivity in the solvent.

Chemical reaction can occur in any of the five regions shown in Figure 2, i.e., the bulk of each phase, the film in each phase adjacent to the interface, and at the interface itself. Irreversible homogeneous reaction between the consolute component C and a reactant D in phase B can be described as

$$\mathrm{C} + z\mathrm{D} \rightarrow \text{products} \tag{4}$$

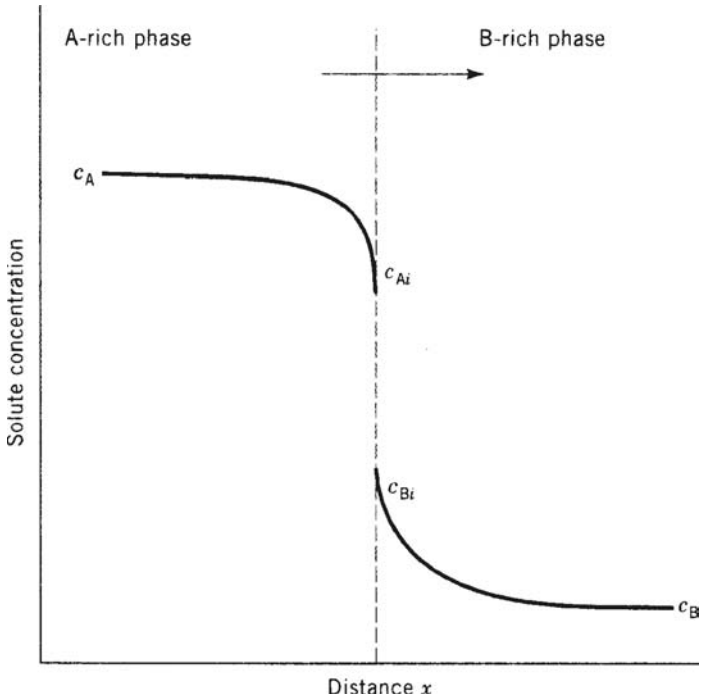

Fig. 2. Concentration profiles near an interface where the arrow represents the direction of mass transfer, c_A = concentration of C in A-rich phase, c_B = concentration of C in B-rich phase, and the subscript i denotes the interface

The equations of combined diffusion and reaction, and their solutions, are analogous to those for gas absorption. It has been shown how the concentration profiles and rate-controlling steps change as the rate constant increases. When the reaction is very slow and the B-rich phase is essentially saturated with C, the mass-transfer rate is governed by the kinetics within the bulk of the B-rich phase. This is defined as regime 1. For a slow reaction defined as regime 2, the consolute component C is almost entirely depleted in the bulk of the B-rich phase and the mass transfer of C between the phases controls the rate of the reaction. For a very fast reaction the depletion of C affects the concentration profile in the diffusion film. The steepening of the concentration profile for regime 3 leads to an enhancement in the film mass-transfer coefficient in the B-rich phase. Finally, the case of an instantaneous reaction (regime 4) leads to the formation of a thin reaction zone to which components C and D diffuse in stoichiometric amounts.

Experimental extraction cells such as the original Lewis stirred cell are often operated with a flat liquid–liquid interface the area of which can easily be measured. In the single-drop apparatus, a regular sequence of drops of known diameter is released through the continuous phase. These units are useful for the direct calculation of the mass flux N and hence the mass-transfer coefficient for a given system. In industrial equipment, however, it is usually necessary to create a dispersion of drops in order to achieve a large specific interfacial area, a, defined as the interfacial contact area per unit volume of two-phase dispersion. Thus the mass-transfer rate obtainable per unit volume is given as

$$(N \cdot a) = K_A a(c_A - c_A^*) \tag{5}$$

Multistage contacting can be arranged in a concurrent, crosscurrent, or countercurrent manner. The sequence of stages is sometimes referred to as a cascade, referring to the early use of gravity overflow from stage to stage. The countercurrent arrangement represents the best compromise between the objectives of high extract concentration and a high degree of extraction of the solute, for a given solvent-to-feed ratio. For the case of a partially miscible ternary system, the number of ideal stages in a countercurrent cascade can be estimated graphically on a triangular diagram, using the Hunter-Nash method.

Fractional extraction is the separation of two or more consolute components by solvent extraction. Single-solvent fractional extraction has been known for many years, but the range of solvents available is limited because of the requirement that the solvents must be sparingly miscible with each of the feed components.

Dual solvent fractional extraction makes use of the selectivity of two solvents (A and D) with respect to consolute components.

Although the equilibrium stage concept has proved extremely useful in describing the performance of mixer-settlers and plate columns having discrete stages, it is not appropriate for spray towers, packed columns, etc, in which no discrete stages can be identified. In such differential types of contactors, equilibrium between phases is never reached and therefore the mass-transfer rate is important in the design procedure.

A differential countercurrent contactor operating with a dilute solution of the consolute component C and immiscible components A and B is shown in Figure 3. Under these conditions, the superficial velocities of the A-rich and B-rich streams can be assumed not to vary significantly with position in the contactor, and are taken to be U_A and U_B, respectively. The concentration of C in the A-rich stream is c_A and that in the B-rich stream is c_B.

A steady-state material balance can be carried out on a small section of length dz and volume dz (on the basis of unit cross-sectional area) in the contactor:

$$U_B dc_B = U_A dc_A = K_A a(c_A - c_A)dz \tag{6}$$

Elementary texts assume that all the fluid in each phase has the same resident time in a countercurrent extractor. In practice, the two phases rarely move countercurrently in plug flow because of axial mixing which arises from the action of turbulent eddies, circulation currents, or the effects of drop wakes. The effect is to flatten the axial concentration profiles within each phase. Axial mixing can lead to a reduction in the effective driving force for mass transfer which in turn reduces the NTU below that expected for the plug flow case. An important feature of the profile is the discontinuity or "jump" in concentration which occurs at entry to the contactor when the liquid in the feed line enters the mixed region of the column.

Two alternative approaches are used in axial mixing calculations. For differential contactors, the axial on model is used:

$$N = -E\frac{\partial c}{\partial z} \tag{7}$$

For contactors in which discrete well-mixed compartments can be identified, for example sieve-plate columns, axial mixing effects are incorporated into the stagewise model by means of the backflow ratio α which is defined

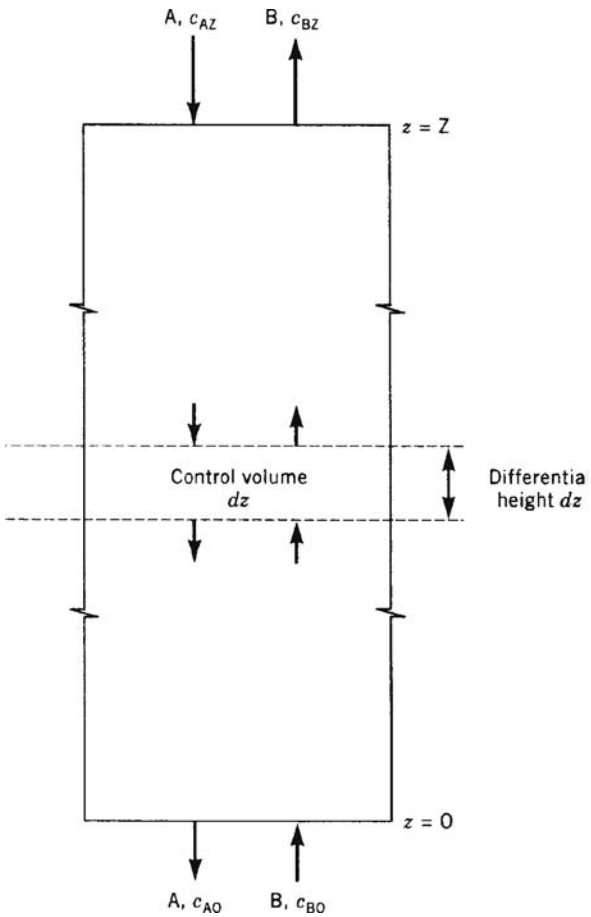

Fig. 3. Mass transfer in a differential contactor. Terms are defined in the text

as the fraction of the net interstage flow of one phase which is considered to flow in the reverse direction. For a contactor in which there are many compartments, the axial dispersion coefficient and the backflow ratio, α, are interrelated as follows:

$$E = \frac{UH}{\ln((1+\alpha)/\alpha)} \tag{8}$$

where H is the height of one compartment and U is the superficial velocity. The detailed calculations of concentration profiles and mass-transfer rates with axial mixing require the solution of a fourth-order differential equation (dispersion model) or the equivalent difference equation (backflow model) along with appropriate boundary conditions.

In extraction equipment, drops are initially formed at distributor nozzles; in some types of plate column the drops are repeatedly formed at the perforations on each plate. Under such conditions, the diameter is determined primarily by the balance between interfacial forces and buoyancy forces at the orifice or perforation.

In many types of contactors, such as stirred tanks, rotary agitated columns, and pulsed columns, mechanical energy is applied externally in order to reduce the drop size and thereby increase the rate of mass transfer.

The volume fraction of the dispersed phase, commonly known as the holdup h, can be adjusted in a batch extractor by means of the relative volumes of each liquid phase added. However, in a countercurrent column contactor, the holdup of the dispersed phase is considerably less than this, because the dispersed drops travel quite fast through the continuous phase and therefore have a relatively short residence time in the equipment. The holdup is related to the superficial velocities U of each phase, defined as the flow rate per unit cross section of the contactor, and to a slip velocity U_s:

$$U_s = U_d/h + U_c/(1-h) \tag{9}$$

As the throughput in a contactor represented by the superficial velocities U_c and U_d is increased, the holdup h increases in a nonlinear fashion. A flooding point is reached at which the countercurrent flow of the two liquid phases cannot be maintained. The flow rates at which flooding occurs depend on system properties, in particular density difference and interfacial tension, and on the equipment design and the amount of agitation supplied.

The nonuniformity of drop dispersions can often be important in extraction. This nonuniformity can lead to axial variation of holdup in a column even though the flow rates and other conditions are held constant.

Coalescence between adjacent drops and between drops and contactor internals is important for two reasons. It usually plays a part, in combination with breakup, in determining the equilibrium drop size in a dispersion, and it can therefore affect holdup and flooding in a countercurrent extraction column. Secondly, it is an essential step in the disengagement of the phases and the control of entrainment after extraction has been completed.

An extraction technique which uses a thin liquid membrane or film has been introduced. The principal advantages of liquid-membrane extraction are that the inventory of solvent and extractant is extremely small and the specific interfacial area can be increased without the problems which accompany fine drop dispersions. See also **Membrane Separations Technology**.

The use of a supercritical fluid such as carbon dioxide as extractant is growing in industrial importance, particularly in the food-related industries. The advantages of supercritical fluids as extractants include favorable solubility and transport properties, and the ability to complete an extraction rapidly at moderate temperature.

Liquid–liquid extraction usually involves an aqueous phase and an organic phase, but systems having two or more aqueous phases can also be formed from solutions of mutually incompatible polymers such as poly(ethylene glycol) (PEG) or dextran.

Because of the growth in biotechnology, two-phase aqueous extraction is becoming more important industrially. Two-phase aqueous systems have low interfacial tension, low interphase density difference, and high viscosity in comparison with most aqueous–organic systems. Although interfacial contact is very efficient, the separation of the phases after contact can be slow, requiring centrifugation. The performance of a spray column for two-phase aqueous extraction has also been reported.

Equipment and Processing

Several laboratory units are useful in analysis, process control, and process studies. The AKUFVE contactor incorporates a separate mixer and centrifugal separator. It is an efficient instrument for rapid and accurate measurement of partition coefficients, as well as for obtaining reaction kinetic data. Miniature mixer–settler assemblies set up as continuous, bench-scale, multistage, countercurrent, liquid–liquid contactors are particularly useful for the preliminary laboratory work associated with flow-sheet development and optimization because these give a known number of theoretical stages.

Because the factors relating to mass transfer and fluid dynamics of the systems in an extractor are extremely complex, particularly for mixed solvents and feedstocks of commercial interest, pilot-scale testing remains an almost inevitable preliminary to a full-scale contactor design. These tests provide *(1)* total throughput and agitation speed; *(2)* HETS or HTU; *(3)* stage efficiency; *(4)* hydrodynamic conditions, such as droplet dispersion, phase separation, flooding, emulsion layer formation, etc; *(5)* selection of direction of mass transfer; *(6)* solvent-to-feed ratio; *(7)* material of construction and its wetting characteristics; and *(8)* confirmation of the desired separation in cases where equilibrium data are not available.

For design of a large-scale commercial extractor, the pilot-scale extractor should be of the same type as that to be used on the large scale. Reliable scaleup for industrial-scale extractors still depends on correlations based on extensive performance data collected from both pilot-scale and large-scale extractors covering a wide range of liquid systems. Only limited data for a few types of large commercial extractors are available in the literature.

Extractors can be classified according to the methods applied for interdispersing the phases and producing the countercurrent flow pattern.

Organic Processes

The first large-scale application of extraction was the removal of aromatics from kerosene [CAS: 8008-20-6] to improve its burning properties. Solvent extraction is also extensively used to meet the growing demand for the high purity aromatics such as benzene, toluene, and xylene (BTX) as feedstocks

for the petrochemical industry. Additionally, the separation of aromatics from aliphatics is one of the largest applications of solvent extraction. See also **Petrochemicals**; and **Petroleum Refining**.

The pharmaceutical industry is a principal user of extraction because many pharmaceutical intermediates and products are heat-sensitive and cannot be processed by methods such as distillation.

Antibiotics. Solvent extraction is an important step in the recovery of many antibiotics such as penicillin [CAS: 1406-05-9], streptomycin [CAS: 57-92-1], novobiocin [CAS: 303-81-1], bacitracin [CAS: 1405-87-4], erythromycin, and the cephalosporins. A good example is in the manufacture of penicillin by a batchwise fermentation. Amyl acetate [CAS: 628-63-7] or *n*-butyl acetate [CAS: 123-86-4] is used as the extraction solvent for the filtered fermentation broth. The penicillin is first extracted into the solvent from the broth at pH 2.0 to 2.5 and the extract treated with a buffer solution (pH 6) to obtain a penicillin-rich solution. Then the pH is again lowered and the penicillin is re-extracted into the solvent to yield a pure concentrated solution. Because penicillin degrades rapidly at low pH, it is necessary to perform the initial extraction as rapidly as possible; for this reason centrifugal extractors are generally used.

Vitamins. The preparation of heat-sensitive natural and synthetic vitamins involves solvent extraction. Natural vitamins A and D are extracted from fish liver oils and vitamin E from vegetable oils; liquid propane [CAS: 74-98-6] is the solvent. In the synthetic processes for vitamins A, B, C, and E, solvent extraction is generally used either in the separation steps for intermediates or in the final purification.

Food processing makes use of solvent extraction in several ways. Industrial refining of fats and oils using propane is known as the Solexol process. Solvent extraction is used in many protein refining processes, for example the extraction of fish protein from ground fish using *i*-propyl alcohol. Recovery of lactic acid by an extractive fermentation has recently been reported. The applications of extraction in the food industry have been reviewed.

Solvent extraction has found application in the coal-tar industry for many years, as for example in the recovery of phenols from coal-tar distillates by washing with caustic soda solution. Solvent extraction of fatty and resimic acid from tall oil has been reported. Dissociation extraction is used to separate *m*-cresol from *p*-cresol and 2,4-xylenol from 2,5-xylenol. Solvent extraction can play a role in the direct manufacture of chemicals from coal, treatment of industrial effluents, biopolymer extraction, and difficult separations.

Inorganic Processes

The first significant application of liquid–liquid extraction in inorganic chemical technology was the separation of uranium and plutonium from nuclear reactor fission products in the late 1940s. A few years later, extraction was successfully applied at the front end of the nuclear fuel cycle in separating uranium from ore leach liquors as an alternative to ion exchange. Since then, many other hydrometallurgical applications of liquid–liquid extraction have been developed as well as a number of applications involving nonmetallic inorganic products.

Most inorganic compounds are insoluble or sparingly soluble in organic solvents, whereas metal ions in aqueous solution are stable because water has a high dielectric constant and because of the solvation of ions by water molecules. Aqueous affinity must be overcome usually by an extractant which can react with the metal ion to displace the solvated water and form an uncharged species having significant solubility in the organic solvent. The organic carrier solvent, or diluent, is usually regarded as being chemically inert although the relative aliphatic–aromatic content of the diluent can affect the extraction rates and equilibria. Physical properties of the carrier solvent should include a low viscosity, low flash point, and low vapor pressure to minimize evaporative losses. The interfacial tension between the extractant–diluent phase and the aqueous phase should preferably be high in order to provide good phase separation and minimize entrainment losses. For reasons of cost, the carrier solvent is usually a cut from petroleum distillation having flash points in the 40–80 °C range.

Spent fuel from a nuclear reactor contains ^{238}U, ^{235}U, ^{239}Pu, ^{232}Th, and many other radioactive isotopes (fission products). Reprocessing involves the treatment of the spent fuel to separate plutonium and unconsumed uranium from other isotopes so that these can be recycled or safely stored. See also **Nuclear Power Technology**.

Liquid–liquid extraction is used as an alternative or as a sequel to ion exchange in the selective removal of uranium [CAS: 7440-61-1] from ore leach liquors. These liquors differ from reprocessing feeds in that they are relatively dilute in uranium and only slightly radioactive, and contain sulfuric acid rather than nitric acid.

The recovery of copper [CAS: 7440-50-8], Cu, from ore leach liquors as a stage in the hydrometallurgical route to the pure metal is one of the largest applications of liquid–liquid extraction.

Often present with copper in sulfuric acid leach liquors are nickel [CAS: 7440-02-0] and cobalt [CAS: 7440-48-4]. In the case of chloride leach liquors, separation of cobalt from nickel is inherently simpler because cobalt, unlike nickel, has a strong tendency to form anionic chloro-complexes. Thus cobalt can be separated by amine extractants, provided the chloride content of the aqueous phase is carefully controlled. A successful example of this approach is the Falconbridge process developed in Norway.

Because of the large number of chemical extractants available, virtually any metal can be extracted from its aqueous solution. In many cases extraction has been developed to form part of a viable process.

Phosphoric acid is usually formed from phosphate rock by treatment with sulfuric acid, which forms sparingly soluble calcium sulfate from which the phosphoric acid is readily separated. However, in special circumstances it may be necessary to use hydrochloric acid.

EXTRACTION (LIQUID-SOLID). Liquid–solid extraction or leaching is a unit operation that predates large-scale industrial operations, with a history of known uses that goes back to Roman times. The early leaching process was known as lixiviation, a term used to describe the extraction of alkaline salts from wood and other plants. The term leaching, in use in the eighteenth century, was used to describe the process of percolating a liquid through a solid material. It is presumed that a soluble component was removed from the solid phase during the percolation so that the operation was distinguishable from sand filters which were quite widely used by that date, but which served a quite different function. Extraction is used in a wide variety of process industries and traditional terms have evolved in different fields. These include leaching, washing, percolation, digestion, steeping, lixiviation, and infusion, among others.

Many substances used in modern processing industries occur in a mixture of components dispersed through a solid material. To separate the desired solute constituent or to remove an unwanted component from the solid phase, the solid is contacted with a liquid phase in the process called liquid–solid extraction, or simply leaching. In leaching, when an undesirable component is removed from a solid with water, the process is called washing.

In the biological and food processing industries, many products are extracted from their original structure by liquid–solid extraction. Sugar is extracted from sugar beets using hot water. Instant coffee is leached from ground roasted coffee using water. Soluble tea is leached from tea leaves. See also **Food Processing**. Pharmaceutical components, flavors, and essences are leached from plant roots, leaves, and stems; and oil is extracted from peanuts, soybeans, sunflower and cotton seeds, and halibut livers by solvents such as hexane, acetone, or ether. These are all examples of liquid–solid extraction. See also **Flavors and Essences**; and **Pharmaceuticals**;

Large-scale leaching also occurs in the metal processing industries, where useful metals frequently occur mixed with large quantities of unwanted matter, and leaching is used to remove the metals as soluble salts. For example, gold is leached from its ore using aqueous sodium cyanide solutions; cobalt and nickel by sulfuric acid–ammonia–oxygen mixtures; and copper salts by sulfuric acid or ammoniacal solutions.

Mechanisms of Extraction

If the solute is uniformly distributed through the solid phase the material near the surface dissolves first to leave a porous structure in the solid residue. In order to reach further solute the solvent has to penetrate this outer porous region; the process becomes progressively more difficult and the rate of extraction decreases. If the solute forms a large proportion of the volume of the original particle, its removal can destroy the structure of the particle, which may crumble away, and further solute may be easily accessed by solvent. In such cases the extraction rate does not fall as rapidly.

In general, the following steps can occur in an overall liquid–solid extraction process: solvent transfer from the bulk of the solution to the surface of the solid; penetration or diffusion of the solvent into the pores of the solid; dissolution of the solvent into the solute; solute diffusion to the surface of the particle; and solute transfer to the bulk of the solution. The various fundamental mechanisms and processes involved in these steps make it impracticable or impossible to describe leaching by any rigorous theory.

Any one of the five basic processes may be responsible for limiting the extraction rate. The rate of transfer of solvent from the bulk solution to the solid surface and the rate into the solid are usually rapid and are not rate-limiting steps and the dissolution is usually so rapid that it has only a small effect on the overall rate. However, knowledge of dissolution rates is sparse and the mechanism may be different in each solid.

The overall extraction process is sometimes subdivided into two general categories according to the main mechanisms responsible for the dissolution stage: *(1)* those operations that occur because of the solubility of the solute in or its miscibility with the solvent, e.g., oilseed extraction, and *(2)* extractions where the solvent must react with a constituent of the solid material in order to produce a compound soluble in the solvent, eg, the extraction of metals from metalliferous ores. In the former case the rate of extraction is most likely to be controlled by diffusion phenomena, but in the latter the kinetics of the reaction producing the solute may play a dominant role.

Diffusion and Mass Transfer During Leaching. Rates of extraction from individual particles are difficult to assess because it is impossible to define the shapes of the pores or channels through which mass transfer has to take place. However, the nature of the diffusional process in a porous solid could be illustrated by considering the diffusion of solute through a pore. This is described mathematically by the diffusion equation, the solutions of which indicate that the concentration in the pore would be expected to decrease according to an exponential decay function.

Process Design

In most leaching operations the maintenance of constant fluid flows, pressures, and temperatures are important. These, together with the need to provide a sufficient contact time between the solvent and the solids, usually indicate a need for continuous, multistage, countercurrent processes in which fresh solvent is fed to the final stage while the solids are fed to the first stage. The objective is to be able to operate at steady conditions, and to be able to avoid extraction of undesirable material while preventing loss of solvent for both economic and safety reasons. This is usually achieved through the use of the usual control equipment, and recording instruments provide a useful means of studying plant performance. There are other factors which must be taken into account in the early stages of a design such as the particle size of the solid and the solvent employed.

Particle Size. The smaller the particle size, the greater is the relative interfacial area between the solid and the liquid and the shorter are diffusional path lengths, and therefore the higher is the rate of transfer of solute. However, smaller particle sizes tend to lead to lower drainage rates from the solid residue and can create problems in the solids flow through countercurrent extraction equipment. A compromise has to be made to select a particle size, which offers an acceptable extraction rate but yet does not unduly impede flow of solvent through a percolation process or of solids through a countercurrent process. If the extractable material is a minor proportion of the starting material, the disposal of the solids residue may present a problem. If the residues have some commercial value as a product after further processing, excessive grinding of the feed solids may render the residue unsuitable for the product and hence have an adverse effect on the economics of the extraction process.

Solvent. Solvent choice is determined by the chemical structure of the material to be extracted, and the rule that like dissolves like provides useful guidance. Thus vegetable oils consisting of triglycerides of fatty acids are normally extracted with hexane [CAS: 110-54-3], whereas for free fatty acids, which are more polar than the triglycerides, more polar alcohols are used. Halogenated hydrocarbons and hexane are both widely used as solvents, and liquid carbon dioxide [CAS: 124-38-9] appears to be suitable for extracting flavor components from plants. Where a choice of solvent other than water exists on the grounds of comparable solubility of the solute, the following criteria are likely to be considered.

Selectivity. Solvent selectivity is intimately linked to the purity of the recovered extract, and obtaining a purer extract can reduce the number and cost of subsequent separation and purification operations. In aqueous extractions pH gives only limited control over selectivity; greater control can be exercised using organic solvents. Use of mixed solvents, for example short-chain alcohols admixed with water to give a wide range of compositions, can be beneficial in this respect.

Physical Properties. Low surface tension facilitates wetting of the solids in the first extraction stage, and low viscosity assists diffusion rates in the solvent phase. A low solvent density is desirable to reduce the mass of solvent held up in the solid being extracted, but solvent choice is usually dictated by other factors. A high boiling solvent with a high latent heat of evaporation requires recovery conditions that may be adverse for thermally sensitive extracts and increases the cost of solvent recovery. In chemical leaching the thermodynamics of the leaching reaction must be considered in terms of the redox potential–pH diagram (Pourbaix diagram) which can be constructed from standard free-energy data. This provides the basis for choosing equilibrium leaching conditions (acidic vs basic, oxidizing vs reducing), leaving the need for a kinetic study to provide data on leaching rates.

Thermal Stability. At processing temperatures in both the extraction and recovery plants the solvent should be completely stable to avoid expensive solvent losses; contamination of the solvent by any solvent breakdown products must be avoided.

Hazards. The solvent should be nontoxic and nonhazardous; adequate design must take into account flammability and explosivity characteristics of the solvent.

Temperature. Both the solubility of the material being extracted and its diffusivity usually increase with temperature, and higher extraction rates are obtained. In some cases the upper limit for the operating temperature is determined by factors such as the need to avoid undesirable side reactions.

Agitation of the Fluid. Agitation of the solvent increases local turbulence and the rate of transfer of material from the surface of the particles to the bulk of the solution. Agitation should prevent settling of the solids, to enable most effective use of the interfacial area.

Equilibrium Relationships and Mass Balances

The solid can be contacted with the solvent in a number of different ways but traditionally that part of the solvent retained by the solid is referred to as the underflow or holdup, whereas the solid-free solute-laden solvent separated from the solid after extraction is called the overflow. The holdup of bound liquor plays a vital role in the estimation of separation performance. In practice both static and dynamic holdup are measured in a process study, other parameters of importance being the relationship of holdup to drainage time and percolation rate. The results of such studies permit conclusions to be drawn about the feasibility of extraction by percolation, the holdup of different bed heights of material prepared for extraction, and the relationship between solute content of the liquor and holdup.

Single-Stage Leaching. A single-stage leaching process is shown in Figure 1. The solution overflow rate is V kg/h; the mass fraction of solute in the overflow solution is x_A; and the liquid in the slurry is flowing at L kg/h, and has a composition y_A. The mass flow of dry inert solids in the slurry is B kg/h.

The material balance equations are, for the total solution:

$$L_0 + V_2 = L_1 + V_1 = M \tag{1}$$

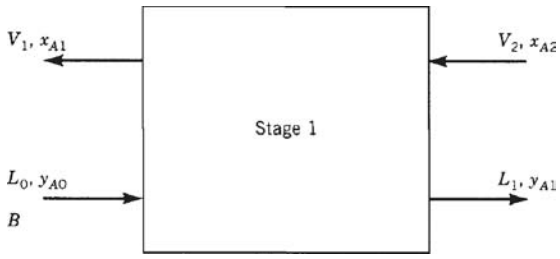

Fig. 1. Flow diagram for single-stage leaching

where M is the total input flow rate of solution to the unit; for the solute component A:

$$L_0 y_{A0} + V_2 x_{A2} = L_1 y_{A1} + V_1 x_{A1} = M x_{Am} \tag{2}$$

where $x_1 = y_1 = x_{Am}$; and for the solids:

$$B = L_0 N_0 = L_1 N_1 \tag{3}$$

where N_i is the mass concentration of inert solids in the ith stream, i.e., kg of inert solid per kg solution. From these balances the concentration of the discharged solution can be estimated.

Countercurrent Multistage Leaching. Countercurrent extraction offers the most economical use of solvent, permitting high concentrations in the final extract and high recovery from the initial solid but utilizing the least amount of solvent. When the amount of solvent removed with the insoluble solid in the underflow is constant, it is convenient to define the ratio

$$R = \frac{\text{amount of solvent in overflow}}{\text{amount of solvent in underflow}} = \frac{V_n}{L_n} \tag{4}$$

If perfect mixing occurs in each stage and the solute is not adsorbed preferentially at the surface of the solid, then the concentration of the solution in the underflow is the same as that in the overflow and

$$R = \frac{\text{amount of solute in overflow}}{\text{amount of solute in underflow}} = \frac{V_n x_{An}}{L_n y_{An}} \tag{5}$$

Referring to Figure 2, by considering solute mass balances over n, $(n-1), \ldots 2, 1$ units in turn and eliminating intermediate solute mass fractions and flow rates, the amount of solute associated with the leached solid may be calculated in terms of the composition of the solid and solvent streams fed to the system. The resulting equation is

$$L_0 y_{A0} = \frac{R^{n+1} - 1}{R - 1} L_n y_{An} - \frac{R^n - 1}{R - 1} V_{n+1} x_{An+1} \tag{6}$$

Countercurrent Leaching with Variable Underflow. In practice most applications have a variable underflow, which is normally greatest at that point in the process where the solute concentration in the solvent is highest.

Extractors

The variety of extractors used in liquid–solid extraction is diverse, ranging from batchwise dump or heap leaching for the extraction of low grade ores to continuous countercurrent extractors to extract materials such as oilseeds and sugar beets where problems of solids transport have dominated equipment and development.

Safety and Environmental Considerations

Solvent flammability, the solvent, and dust loading in the atmosphere of the working environment and of the products in the case of edible materials are the main factors that constitute health and safety hazards in extraction plants. General safety and environmental standards must therefore be applied and due recognition taken of the most recently published national regulations relating to acceptable threshold limit values (TLVs) for solvents and dusts.

Disposal of exhausted solids can be easily overlooked at the plant design stage, particularly when these have no intrinsic value; alternative disposal methods might include landfill of inert material or incineration, hydrolysis, or pyrolysis of organic materials. Liquid, solid, and gaseous emissions are all subject to the usual environmental considerations.

EXTRACTIVE METALLURGY. That phase of metallurgy dealing with the removal of metals from minerals. Methods are discussed under individual metals.

EXTRAEMBRYONIC MEMBRANES. A series of structures developed in connection with the embryos of vertebrates (reptiles, birds and mammals), but not as parts of the body itself. They relate the embryo to its environment in several ways. These membranes are the allantois, amnion, chorion, serosa, and yolk sac.

EXTRANETS. Extranets provide the means to extend information stored on internal networks (intranets) to external audiences. External groups often include suppliers, vendors, or customers. Allowing business partners to access internal information provides a foundation for e-commerce strategies, improves collaboration, and can result in faster time to market for new products. Access to organizational extranets also promotes internal efficiencies and cost reduction. Developing extranet applications requires careful planning of the applications and content management, defining classes of external organizations that can access internal information through the extranet, and security policies to protect the network and information resources.

The Internet is a wide-area network that consists of thousands of organizational networks worldwide. The Internet became popular in the 1990s with the advent of the "World Wide Web." See also **Internet (The History)**. The Web provides information stored on servers that are connected to the Internet. Web browsers, such as Netscape Navigator and Microsoft Internet Explorer, provide interfaces to interpret and display the Web pages. Documents accessible on the Web contain hyperlinks to move from one document to another. The benefits of the Internet include the ability to discover information more quickly and in larger volumes as well as increased opportunities for communication with individuals and groups. It is hard to imagine an organization today that does not have access to the Internet or does not maintain its own organizational Web site. In the early days of the Internet, an organizational presence on the Web provided a competitive advantage. Today, an organization's presence on the Web is an essential part of doing business.

The benefits of Internet technology and Web browsing led to the creation of organizational networks that provide restricted access for internal employees. The internal networks became known as "intranets", private enterprise networks that use the Internet and Web technologies for information gathering and distribution within the organization. By converting old applications or writing new applications for use on an intranet, organizations can eliminate dependence on a particular operating system/platform.

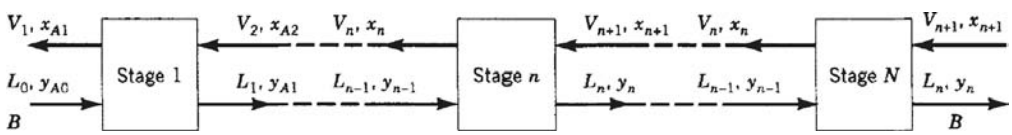

Fig. 2. Flow diagram for countercurrent multistage leaching

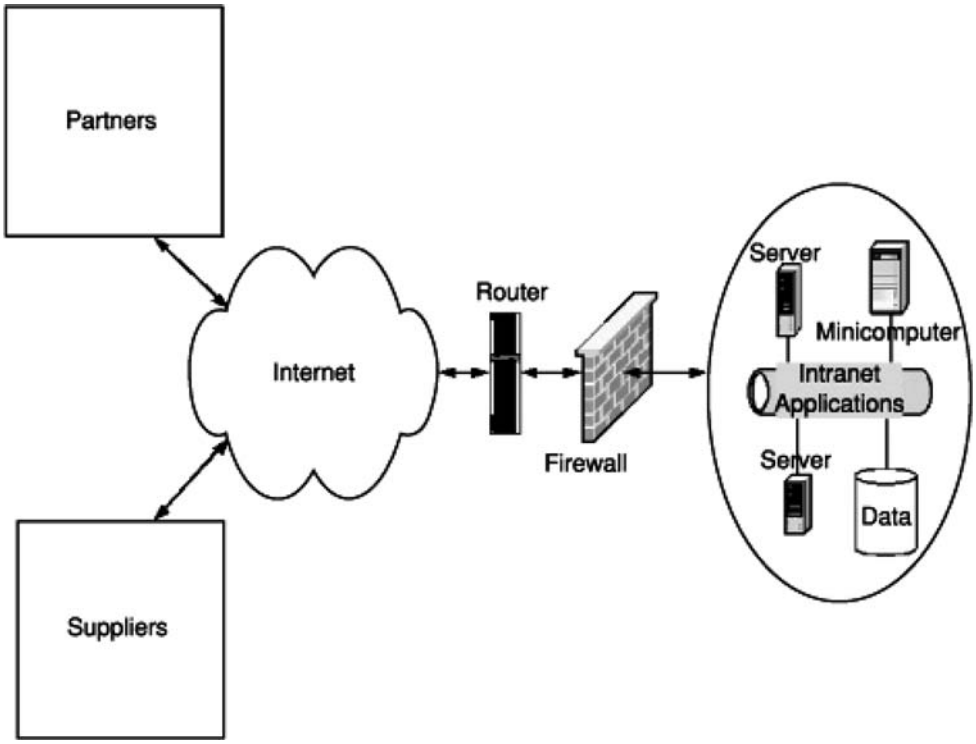

Fig. 1. Organizational extranet

The intranet has also become an effective communication vehicle to share information within the organization. The intranet provides easy access to internal information that can be published by departments within the organization. Other applications supported by the intranet include employee access to legacy systems, Web sites for human resources, payroll information, and even training programs. Intranets support collaborative processes between departments, such as scheduling, messaging, and discussion groups. Intranets can also empower customer support center staff with intranet knowledge management systems that result in improved customer satisfaction. Through the use of intranets, organizations have reduced costs while also increasing employee productivity.

The intranet is typically protected from the public Internet by a firewall, a device that acts as a gatekeeper between the organizational intranet and the outside Internet. The firewall permits internal employees to access the public Internet, but it prevents outside users (the public) from accessing the internal resources of the organization. See also **Fireball**.

A natural extension of the intranet would allow selected external entities to access internal organizational resources. An "extranet" provides a collaborative network that uses Internet technologies to extend intranet applications and services to selected external organizations, thereby creating a community of interest beyond the walls of the organization. In addition, providing remote access to the intranet permits employees who are off site to access intranet services; for example, employees working from home could access intranet resources through the deployment of an extranet. The extranet is typically not available to the general public but rather it is limited to "strategic partners." These strategic partners may include suppliers, vendors, customers, or other organizations involved in collaborative research and development. Bringing suppliers, partners, and even customers into the information loop is critical to developing a company's quick response and strategic movement as it adapts to an evolving market environment. Figure 1 depicts an organizational extranet.

Extranets can fundamentally change how organizations share internal resources and interact with outside suppliers, customers, and strategic business partners. The implementation of an extranet can be effective in developing tighter linkages in supply chain management and customer relationship management. The current trends suggest an increasing movement toward developing these linkages through extranet applications. Extranets provide a cost effective means to improve collaboration and decrease the time to market for new products. Moreover, extranets can increase internal efficiencies within the organization. As the extranet examples have shown, applications for extranet deployment are not isolated to one type of industry. Extranets can be effective in seizing a competitive advantage in virtually any type of industry.

The implementation of an extranet solution for any business requires careful planning and a shift in business and management philosophy. Moreover, opening the corporate intranet requires careful assessment of security precautions, defining the external audiences who should have access, and establishing policies for content management.

See also **Intranets**.

EXTRAORDINARY INDEX. The refractive index for the extraordinary ray in a crystal showing double refraction, measured perpendicular to the optic axis (in which direction its value differs most from the index for the ordinary component). If an unpolarized ray of light strikes the surface of calcite or other crystal normally showing double refraction it will be divided into two transmitted rays. One ray, the ordinary, will not be bent, while the other ray, the extraordinary, will be bent on entering the crystal. Rotation of the crystal about the entrant ray causes the extraordinary ray to rotate about the ordinary ray.

EXTRAORDINARY RAY. The refracted component of a beam of radiation split by having passed through a doubly refracting substance. The other component is called the ordinary ray.

EXTRATERRESTRIAL LIFE. Life forms evolved and existing outside the terrestrial biosphere.

EXTRATERRESTRIAL MATERIALS. Extraterrestrial materials are samples from other bodies in the solar system that can be studied in earth-bound laboratories. Sensitive and ever-improving analytical techniques are used to provide information at levels of detail and sophistication that cannot be matched by telescopic or spacecraft investigations. Much of the knowledge of early solar system bodies, processes, environments, and chronology has come from the study of these samples. Extraterrestrial materials that are available for laboratory study include meteoritic materials that fall naturally to the earth, some meteoritic material that has been captured in space, and lunar samples that were recovered by the Apollo and Luna sample-return missions flown to the moon during the years 1969

to 1972. The meteoritic materials in existing collections include samples from asteroids, comets, and the moon, and probably Mars. The comet and asteroid samples are the best preserved solids from the early solar system and are the oldest and most cosmochemically primitive samples available for direct study. Because of their primitive and unfractionated nature, these samples provide the best estimate of the composition of the sun and the solar system as a whole. It has been shown that many meteorites contain preserved interstellar grains, particles older than the Sun that formed around other stars and served as the initial building blocks of the solar system.

Meteorites

Meteorites by definition are extraterrestrial materials that fall from the sky and actually hit the surface of the earth. In space they are considered to be meteoroids and during their luminous entry into the atmosphere they are called meteors. Meteorite strictly applies only after impacting the Earth. Conventional meteorites are rocks ranging in size from a centimeter to a few meters. The largest known meteorite is the 70-ton Hoba that resides at its discovery site in South Africa. Larger meteoroids do not sufficiently decelerate from cosmic velocity in the atmosphere and are destroyed upon impact, forming an explosion crater. Meteorites fall randomly to the Earth but are not found randomly distributed on the Earth's surface. The highest general concentrations of meteorites occur in Antarctica, where long exposure time and the combined effects of ice movement and sublimation concentrate meteorites on top of blue ice fields. In Antarctica and elsewhere, meteorites are often found in clusters created by the breakup of a larger body during hypervelocity entry into the atmosphere. When a meteor breaks up at high altitude, the resulting fragments impact over an elliptical region several kilometers across the ground, forming a strewn field where sometimes thousands of individual specimens are found. Because of atmospheric breakup, the number of individual meteorite specimens that are collected is much larger than the actual number of meteoroids that produced them. Meteoroids are themselves fragments of bodies that broke up in space, and the actual lineage of meteoritic samples may trace back to a relatively limited number of initial parent bodies. See also **Meteoroids and Meteorites**.

Most meteorites can be classified into definite groups distinguished by elemental, mineralogical, petrographic, and isotopic composition. The general groups are the chondrites, achondrites, irons, and stony irons. Although fragments of one meteorite class are often found inside another as a result of collisional mixing, in general the bulk properties of meteorites fall into quantified groups without a continuum of compositions between established groups. It is likely that some groups are samples of single asteroids, the apparent source of most meteorites. The majority of asteroids are located in the asteroid belt between Jupiter and Mars, and are believed to be relic solar nebula planetismals that escaped incorporation into planets.

Over 90% of the meteorites that are observed to fall out of the sky are classified as chondrites, samples that are distinguished from terrestrial rocks in many ways. One of the most fundamental is age. Like most meteorites, chondrites have formation ages close to 4.55 Gyr. Chondrites also have basically undifferentiated elemental compositions for most nonvolatile elements and match solar abundances except for moderately volatile elements. The most compositionally primitive chondrites are members for the type 1 carbonaceous (Cl) class.

Another unique property of chondrites is the presence of chondrules, objects found in nearly all chondrites except those of the CI class. Chondrules are millimeter-sized, spheroidal bodies composed predominantly of olivine, $(Mg, Fe)_2SiO_4$, pyroxene, and a glass of approximate feldspathic composition. It is believed that these were objects individually orbiting the Sun that formed by rapid melting and cooling of millimeter-sized precursors. The processes must have been highly efficient, as chondrules comprise $>75\%$ of the mass of many meteorites. It is possible that chondrules were primary building blocks of the earth and the terrestrial planets.

Chondrites are divided into eight subclasses distinguished by elemental, isotopic, and mineralogical composition. A characteristic distinguishing different chondrite groups is the abundance and oxidation state of iron, Fe. Chondrite classes are also distinguished by their abundances of both volatile and refractory elements and by the oxygen isotope compositions. This remarkable distinction correlates with compositional and mineralogical classification.

Within each chondrite class there are petro graphic grades that relate to alteration processes that occurred within the meteorite parent body. The grades range from 1 to 6, although no class has examples in more than four grades. Grades 3 to 6 represent the effects of thermal metamorphism where the higher number is the more strongly altered. Grades 1 and 2 occur only for the CI and CM chondrites, respectively. CI and CM chondrites have been extensively altered by aqueous alteration in their parent bodies probably as a result of the melting of ice followed by reactions of preexisting phases.

The achondrites are differentiated stony meteorites that are apparently derived from parent bodies that were heated to at least partial melting temperatures. Achondrites do not contain chondrules and do not have elemental compositions that match solar abundances for condensable elements. These materials are old but their properties were more determined by planetary processes such as melting and differentiation than by primary nebular processes, such as condensation and accretion. Many of the achondrite subclasses can be combined into three basic groups: HED, SNC, and lunar groups. The HED group comprises the howardite, eucrite, and diogenite subclasses, which together are responsible for more than 6% of all meteorite falls. The SNC achondrites are composed of the Shergotty, Nakhla, and Chassigny subgroups.

Approximately 4% of meteorite falls are irons. Because they are distinctive rocks and weather relatively slowly, most meteorites that were not seen to fall, but were found accidentally, are irons. Iron meteorites are composed of metallic iron and siderophile elements that fractionated from molten parent bodies. They may have been cores of asteroids or they may have only been localized metal accumulations.

Typical meteorites have formation ages of 4.55 Gyr and exposure ages of only 10^7 years, during which time they existed as meter-sized bodies unshielded to the effects of cosmic rays. With the exception of the SNC (Martian) and lunar meteorites, it is widely believed that most conventional meteorites are asteroid fragments liberated relatively recently by collisions and transferred to the earth by gravitational perturbations. The principal source location is thought to be the zone 2.5 AU (one AU is equal to the mean distance between the Earth and the sun) from the sun where the orbital frequency about the sun is exactly three times that of Jupiter.

Interplanetary Dust

Interplanetary dust particles (IDPs) are the submillimeter-size regime of the solar system meteoroid inventory ranging in size from tens of nanometers to 1000 km in diameter. These particles are short lived in the interplanetary medium because of the effects of self-collisions and orbital decay caused by the drag component of sunlight (the Poynting-Robertson effect). Most of the IDPs that now reach the earth were liberated from comets and asteroids within the last 10^6 years. Over 40,000 tons of IDPs impinge on the earth annually and cumulatively they are the dominant meteoritic mass input on time scales shorter than 10^7 years. Interplanetary dust in the size range of a few micrometers to a millimeter can be collected in and below the atmosphere, and recovered particles provide an important sampling of asteroids and comets. These samples complement conventional meteorites because they include specimens of objects that for a variety of reasons do not either reach the earth or survive atmospheric entry in greater than cm-sized pieces to become conventional meteorites. Dust provides a broader and less biased sampling of interplanetary materials because small samples of fragile materials can survive atmospheric entry without crushing. Additionally, sunlight pressure effects cause all dust beyond the earth's orbit to evolve toward the sun where collisions with earth are possible.

IDPs can be collected in space although the high relative velocity makes nondestructive capture difficult. Below 80 km altitude, IDPs have decelerated from cosmic velocity and collection is not a problem; however, particles that are large or enter a very high velocity are modified by heating.

The flux of 10-μm particles is $1/(m^2 \cdot d)$, a value high enough that these IDPs can be collected directly using high altitude aircraft. The spatial density of 10-μm IDPs at 20-km altitude is $10^{-3}/m^3$. Particles >100 μm fall at a rate of only $1/(m^2 \cdot yr)$ and can only effectively be collected after they have fallen to the ground and concentrated in a surface deposit. The small particles are collected primarily using stratospheric aircraft although they have also been recovered by melting pristine Antarctic ice. The larger IDPs have been collected from deep sediments, Greenland ice, and Antarctic ice, and a few other selected terrestrial environments that allow the extraterrestrial to be efficiently isolated and distinguished from

terrestrial particles. Many of the >100-μm cosmic particles are spherules and their shape assists in making a distinction from other materials.

The most common IDPs are black objects having approximately solar elemental composition except for very volatile elements such as the noble gases. There are particles that deviate strongly from this pattern but they are rare and are usually dominated by a single mineral such as FeS, olivine, or FeNi metal. Most of the particles can be grouped into two classes: one contains hydrated minerals such as serpentine and smectite; the other, ones that are anhydrous.

Individual IDPs are short-lived and the long-term presence of dust in the solar system implies that there must be sources capable of generating the approximately 10^7 kg/s of new dust required to balance losses by collisions, ejection by radiation pressure, and spiraling into the sun owing to the Poynting-Robertson effect. For sizes >10 μm, it has long been known that comets and asteroids are the principal source. Particles are liberated from asteroids by collisions of both asteroids and asteroid debris. Dust from comets is released when solar heating sublimes the ice matrix in comets. Dust is ejected, and because of the effects of light-pressure drag and ejection velocity, it forms the dust tail that can extend to lengths of over 10^8 km. Most of the comet dust that is collectable on the earth is believed to have been derived from the Kuiper belt comets that reside in a flattened distribution extending from the region of the outer planets to distances of a few 100 AU from the sun. The dust from both comets and asteroids is believed to be samples of early solar system materials that have been relatively well preserved over the age of the solar system inside moderately small bodies.

EXTRUSION. A majority of stock plastic shapes (bars, cylinders, special cross sections) are made in this way. Thermoplastic materials are heated in a plasticizing cylinder and by means of a rotating screw are forced through a die to provide the desired cross section. A variation of the process is used for extruding coatings of soft plastic materials over other materials. Almost any profile can be imparted to the product, but of course, variations in profile are limited to two dimensions. The tooling costs for extrusion are low compared with injection molding. Thickness of the material can be controlled quite precisely. Production rates are high.

Certain metals, including aluminum, and various rubbers are also extruded.

Extrusion is also combined with mixing in some applications. In the type of device shown in the Fig. 1. The material is fed as a dry solid, is fluxed in the barrel to form a paste, and then resolidified at the discharge. Action in the barrel is one of shearing, rubbing, and kneading. One continuous screw or two screws rotate in the closely fitting barrel. The work of the screw is augmented by forcing the material through breaker screens and around breaker disks just before the material is forced out through the exit nozzle. Such machines are often used for extruding soft chemical and food mixes which do not require fluxing, as well as for the extrusion of hard plastics, some of which must be fluxed at temperatures above 400 °F (204 °C). Wires can be covered and shapes of intricate cross section can be produced. Plastic resins also are blended in extruders to form pellets for later press and injection molding.

An excellent and detailed summary of the use of extrusion in the plastics and polymer industries is given by J.A. Gibbons, et al. in the "Modern Plastics Encyclopedia," pp. 219–234, McGraw-Hill, New York, 1986.

Extrusion in the Food Industry. Numerous food formulations, as exemplified by spaghetti, macaroni, and other pasta products, are characterized by a uniform cross-sectional shape (round, rectangular, etc.) and length

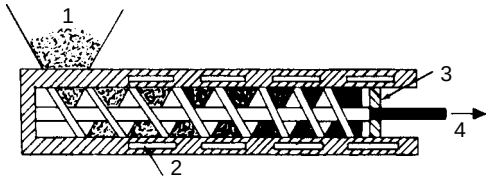

Fig. 1. Mixed-type extruder: (1) Charge stock; (2) heating or cooling chambers in extruder jacket; (3) die; and (4) extruded product.

(rod-like, tube-like, ribbon-like, etc.). These characteristics are imparted by forcing an initial pasty mass through the dies of an extruder. Temperature control of extruding is extremely important. For more detail, reference is suggested to the "Foods and Food Production Encyclopedia," (D.M. and G.D. Considine, Eds.), Van Nostrand Reinhold, New York, 1982.

EXTRUSIVE. A property of an igneous rock that has been ejected onto the earth's surface. Lava flows and detrital material, such as volcanic ash, are extrusives. See also **Mineralogy**.

EYE BAR. A heat-treated tension member formed from a single piece of steel. The finished eye bar consists of a body having a rectangular cross section and two circular heads containing holes for pins, which are used to connect the eye bar when it forms part of a structure. See Fig. 1.

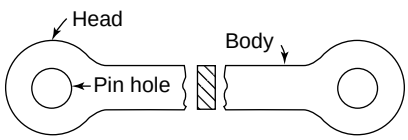

Fig. 1. Eye bar.

In the fabrication of an eye bar, the ends of a steel plate, of the correct cross-sectional area and length, are heated and upset to form the heads. The heads are next rolled to remove any unevenness resulting from the upsetting operation. While the ends are still hot, holes are punched out which are smaller in diameter than the finished pin holes. The bars are then subjected to special heat treatment, which produces a high tensile strength. After cooling, the pin holes are bored to exact size simultaneously.

Eye bars make excellent tension members since the heat treatment enables them to carry higher tensile loads than the ordinary built-up steel members. As the eye bar is a very slender member, it cannot be used where there is a possibility that it will have to carry compressive stress. These members are used in the cable anchorages of suspension bridges. Eye bar chains are sometimes used instead of wire cable for suspension bridges. In the past, eye bars were extensively used for tension members of truss bridges. The use of riveted joints instead of pin-connected joints made eye bars obsolete for such use.

EYE (Human). See **Vision and the Eye**.

EYELID. A fold of skin that can be drawn over the eye in vertebrates more developed than the fishes. Three eyelids are the maximum. These are an upper and lower lid and a third eyelid or nictitating membrane, which passes between the others and the eyeball from the inner to the outer margin of the eye. The eyelids contain glands whose secretion lubricates the apposed surfaces of the lids and eyeball, and in the mammals bears a row of stiff hairs, the cilia or eyelashes.

In humans, *hordeolum* (sty) is a common infection of one or more of the small glands of the eyelids, usually caused by staphylococci. Children are especially susceptible. A sty begins as a small, reddened area on the margin of the lid. Pain is almost always present and is directly related to the amount of swelling. In severe cases, the entire eyelid is swollen. A few days after its appearance, the sty develops a yellow center, caused by the formation of pus, and usually erupts a few days later. A single sty may not require medical attention unless it is quite painful. When a number of sties appear, or when they recur often, general health and diet should be evaluated.

Chalazion is a swelling or enlargement of one of the oil glands of the eyelid. This is caused by obstruction of the gland's duct. The skin moves loosely over the swelling. The physician may prescribe topical medication, but, if this fails, a simple surgical procedure is performed which removes the mass, leaving no visible scar.

Blepharitis is a relatively common condition in which the margins of both eyelids become red and inflamed. Blepharitis can be caused by bacterial infection or it may be an extension of seborrheic dermatitis, involving the scalp, eyebrows, and, at times, the ears. Blepharitis may occur only as redness with slight crusting, or it may cause itching, burning, and edema of the eyelids, lacrimation, and hypersensitivity to light. The lids often become stuck together overnight from the accumulation of dried secretions.

Ptosis is a condition in which one or both upper eyelids droop. This is caused by the failure of the levator muscles of the eyelid to operate properly. The abnormality may be congenital or acquired. Congenital ptosis, when severe, may be treated by surgical alteration of the involved muscles.

Edema of the eyelids usually results from allergies to eyedrops, drugs, or cosmetics. Trichinosis also may produce eyelid edema.

EYE (Meteorological). In meteorology, usually the "eye of the storm" (hurricane, typhoon), that is, the roughly circular area of comparatively light winds found at the center of a severe tropical cyclone and surrounded by the eyewall. The winds increase gradually outward from the center but can remain very light up to the inner edge of the eyewall. No rain occurs and in intense tropical cyclones the eye is clear with blue sky overhead. Most, but not all, tropical cyclones with maximum winds in excess of 40 m s^{-1}(78 knots) have eyes visible on satellite imagery. Eye diameters vary from 10 to more than 100 kilometers (6 to more than 62 miles). See also **Fronts and Storms**.

EYEPIECE. Also known as the *ocular*, the lens, or system of lenses, closest to the eye in an optical instrument such as a telescope or a microscope. The eyepiece is usually a magnifying device used for the purpose of detailed examination of the real image formed by the objective of the instrument. It is usually designed to act as a collimator to the light from the objective, so that the light from each point of the image formed by the objective emerges in parallel or nearly parallel rays. Hence, in using a telescope or microscope in proper adjustment, the eye should be focused as though looking at a distant object.

The simplest type of eyepiece is either a simple convex or concave lens, of relatively short focus, so placed as to serve as a magnifier for the image formed by the objective. Because of the spherical and chromatic aberrations of the simple lens of short focus, a combination of lens is usually employed as an eyepiece. The two most common types of compound eyepieces are the Huygens (Fig. 1) and the Ramsden (Fig. 2). In these eyepieces, the lens *F* is known as the field lens and the lens *E* as the eye lens. The Huygens eyepiece is placed slightly inside the focus of the objective, and the field lens of the eyepiece forms a real image *R* in the plane *S*, from which the rays emerge parallel from *E*. In the Ramsden type, the field and eye lenses combine to render the light from the real image *R*, formed in the plane *S* by the objective, parallel upon emergence from the eyepiece. Since the Huygens type eyepiece is placed inside the principal focus of the objective, a reticle or filar micrometer cannot be used, although a reticle may be placed inside the eyepiece itself in the plane *S*. The Ramsden type, on the other hand, is focused directly upon the plane of the real image from the objective, and a reticle or micrometer may be placed in this plane. Eyepieces of the Ramsden type, which are simple magnifiers focused upon the real image from the objective, are known as positive eyepieces; while eyepieces placed inside the principal focus of the objective, as in the case of the Huygens type, are known as negative eyepieces. (See entries on individual optical instruments for further discussion of positive and negative eyepieces.)

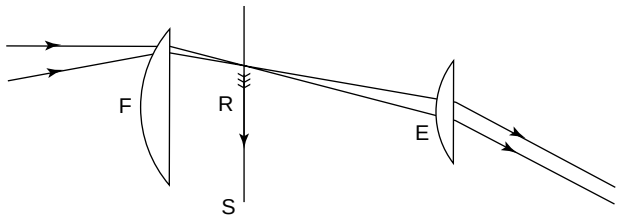

Fig. 1. Huygens eyepiece.

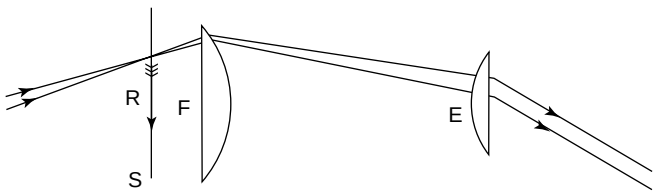

Fig. 2. Ramsden eyepiece.

Both the positive and negative eyepieces give a view of the image from the objective in the same orientation as that image is formed. This means that the observer will see the image of a distant object inverted. Although this is no disadvantage in microscopes and in astronomical telescopes, it is intolerable in a telescope or field glass to be used for observation of distant terrestrial objects. The simple concave lens, as used in the so-called Galilean telescope or opera glass, gives an erect image of a distant object. To avoid the aberrations of the simple concave lens, various "erecting systems" are used in terrestrial telescopes. Some of these erecting systems employ prisms, as in the case of binoculars, or complicated systems of lenses.

EYE (Vertebrate). A sensory organ that is stimulated by light, particularly an organ whose stimulation results in the formation of a mental image of the objects from which the light is reflected or radiated. See Fig. 1.

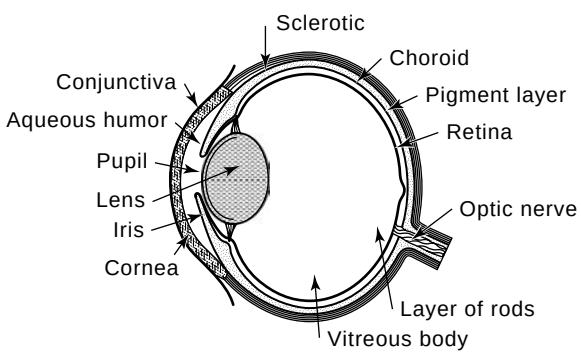

Fig. 1. The vertebrate eye.

Details of the human eye are described under **Vision and the Eye**.

Although most eyes enable the animal to form visual images, that is to see in the usual sense of the word, some light-sensitive organs are capable only of perceiving light and the direction from which it comes. Pigment spots in some of the 1-celled animals are supposed to be light-sensitive and in flatworms and a few insects the eyes are formed of a group of sensitive cells partially isolated by pigment. The structure of these eyes shows no possibility of their forming images.

Eyes of reasonable complexity are found in some of the segmented worms and three types of complex eyes occur in the phyla *Mollusca*, *Arthropoda*, and *Chordata*. These three forms of eyes have been extensively studied and are known in detail.

Arthropod eyes are of two kinds, simple and compound, of which one or both may occur in a single individual. The sensory end organ in both forms is the retinula, a group of visual cells surrounding a central optical rod or rhabdom. In many simple eyes a portion of the cuticula is thickened to form a biconvex lens opposite to a group of retinulae. Compound eyes are made up of many ommatidia, each consisting of a similar lens forming a facet of the cornea of the entire eye, and an underlying retinula, with intervening crystalline cells and, in some species, other structures.

Both mollusks and vertebrates, including, of course, humans, have camera eyes, although their development and structure differ. All camera eyes have a lens suspended before a chamber lined with a sensory layer, the retina. In front of the lens is another chamber and in front of that a transparent cornea which acts as a lens in terrestrial animals. The eye is insulated by a heavily pigmented layer which surrounds it except where the lens is suspended and extends in front of the lens as the iris. The iris, activated by muscles, controls the size of its central opening, the pupil, through which light enters the eye. Light passing through the lens is focused on the retina in a sharp image and the varied stimuli acting on nerve endings result in a definite mental picture. Such eyes are provided with muscles that direct them toward objects to be observed. They also have muscular focusing devices, which move the lens in relation to the retina or vice versa, or control the curvature of the lens as in the human eye.

The action of the different kinds of eyes results in different kinds of vision.

For vision in fishes, see **Fishes**; in snakes, see **Snakes**.

F

FABRIC (Geology). The term proposed by Cross, Iddings, Pirrson, and Washington in 1902 for the shapes and arrangement of crystals in an igneous rock. Best defined as the arrangement of the constituents in a rock, i.e., flow fabric in lava, stratification or bedding in sedimentary rocks; foliation in metamorphic rocks.

FACE-CENTERED CUBIC STRUCTURE. An internal crystal structure, determined by X-rays, in which the equivalent points are at the corners of the unit cell and at the centers of the six faces of a cube.

FACIAL PARALYSIS. See **Bell's Palsy**.

FACIES. In geology, a term for the sum total of the inorganic and organic characteristics of a sedimentary formation. Obviously, different facies of a sedimentary formation (sedimentary time unit) are of the same age; but similar sedimentary facies may represent different formations. Fossils may be useful in determining the age of a facies, provided the types of organisms have not changed with the change in habitat, which, in the case of marine sediments (such as limestones or shale) they usually do. The term facies is also used to designate gradational types of igneous rocks, which are supposed to have been differentiated from a parent magma. See Fig. 1.

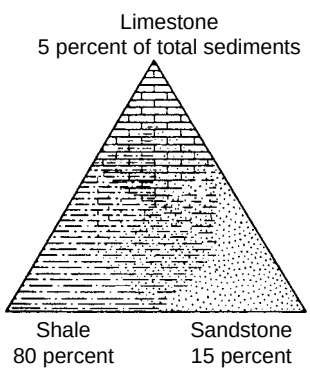

Fig. 1. The relative abundance of the three principal types of sedimentary rocks and their intergradations or facies.

FACIES (Stratigraphy). The sum of all primary lithologic and paleontologic characteristics exhibited by a sedimentary rock, from which its origin and environment of formation may be inferred. It includes the general aspect, nature, or appearance of a sedimentary rock produced under or affected by similar conditions; a distinctive group of characteristics that differs from other groups within a stratigraphic unit. The term is used here in an abstract, descriptive sense for something (such as the "composite character") that a rock has, rather than to designate a particular kind of rock. This usage corresponds closely to the original concept of stratigraphic facies first recognized and defined by Gressly (1838) who, in his studies of Jurassic sedimentary rocks in the eastern Jura Mountains near Solothurn (Switzerland), Gressly used the term "facies" to designate the sum total of the very distinct lateral changes in the interdependent lithologic and paleontologic characteristics of a definite stratigraphic unit (restricted to sedimentary rocks), these characteristics were quite different from those of other facies of the same unit. Later, the concept was broadened (especially in Europe) in a stratigraphically unconfined sense to include vertical changes, so that the sum term referred to the sum of the lithologic and paleontologic characters of a sedimentary deposit at a given place.

Facies is a term that also may refer to an exclusive, mappable, and specific area that is part of a defined stratigraphic rock body, such as a stratum or group of strata differing in lithologic character or fossil contents from other beds deposited at the same time and in physical continuity; a lateral subdivision of a specified stratigraphic unit; or a *lithofacies*. It may be a formally recognized part of a formation, such as the facies, provided with geographic names. Facies of this sort are applied in rock-stratigraphic nomenclature to distinguish lateral variants within the regional distribution of a major mappable stratigraphic unit.

Facies also can refer to an intertonguing sedimentary rock mass (masses) of differing lithologic and paleontologic characteristics. This occurs within a stratigraphic unit, having irregular lateral boundaries, and exhibiting upper and lower limits that do not necessarily correspond with the boundaries of the stratigraphic unit.

Stratigraphic facies may apply to a rock or group of rocks distinguished from other more or less related or comparable rocks of a different appearance or composition. These are identified by any observable feature (except those produced during weathering, metamorphism, or structural disturbance, but sometimes including secondary features resulting from diagenesis). Specifically, the terms applies to any actual body or sediment, or rock of some particular kind or combination of kinds, irrespective of age, form, local geologic relations, and geographic or stratigraphic occurrence (although broadly corresponding to a certain time of environment or common mode or origin). Examples are "red-bed facies," "black-shale facies," "limestone facies," and any other informally designated facies that includes similar rocks, wherever found, at any time.

Stratigraphic facies is a term also applied, especially in Europe, to the environment in which a rock was found or to the environment recorded by a rock body. It is defined according to assumed or generalized environmental conditions or situations (e.g., "eolian facies," "volcanic facies," "marine facies," and "glacial facies"). The term also may reflect climatic conditions, (e.g., "tropical facies," "boreal facies," "littoral facies," and "bathyal facies"). The term also has been used to designate the totality of local geographic and biologic conditions that determine the lithologic and paleontologic nature of the sedimentary rock.

The term also is used in a broad, even vague, sense for paleogeographically or geotectonically defined belts of rock units or sequences (e.g., "geosynclinal facies," "foredeep facies," "orogenic facies," "transverse facies," and "Appalachian facies"). The term may be used to refer to the characteristics of large belts or basins of sedimentation, such as the "nappe facies" of Alpine geology.

FACING. In machining, generating a surface on a rotating workpiece by the traverse of a tool perpendicular to the axis of rotation. In founding, special sand placed against a pattern to improve the surface quality of the casting. *Hard facing* signifies the deposition of filler metal on a surface by welding, spraying, or braze welding to increase resistance to abrasion, erosion, wear, galling, impact, or cavitation damage.

FACSIMILE TRANSMISSION. Although greatly improved, the modern fax machine and copy data transmission system dates back, in principle, for several decades. *Telephoto photographs*, featured mainly in newspapers, appeared in the late 1930s on a limited scale. Wirephoto was another term used. Basically, by way of a scanning procedure, data to be copied are converted into electric signals, transmitted for short or long distances where, upon receipt, the signals are converted to hard copy. Black and color data can be transmitted. See also **Modems**.

FACTOR. The most common use of this term is the mathematical one. If $P(x)$ is a polynomial in one variable of degree n and x_1 is a zero of the polynomial so that $P(x_1) = 0$, then $(x - x_1)$ is one of its factors. In

symbols, $P(x) = a_0 + a_1x + a_2x^2 + \cdots + a_nx^n$; $P(x) = (x - x_1)Q(x)$, where $Q(x)$ is of degree $(n - 1)$. Now $P(x_1) = 0$, hence identically $P(x) \equiv P(x) - P(x_1) \equiv a_1(x - x_1) + a_2(x^2 - x_1^2) + \cdots + a_n(x^n - x_1^n)$ and each term on the right has $(x - x_1)$ as a factor.

Continuing in this way $Q(x)$ can also be reduced to a factor and a term of degree $(n - 2)$. The fundamental theorem of algebra or factor theorem states that there exists one and only one set of constants x_i so that $P(x) = (x - x_1)(x - x_2) \ldots (x - x_n) = 0$. The constants are the roots of $P(x)$.

To factor a polynomial means to find two or more polynomials whose product is the given polynomial.

In statistics, in addition to the above mathematical usage, the term *factor* is used in three other senses: (1) to denote a quantity under examination in an experiment as a possible cause of variation, e.g., in a "factorial" experiment, (2) (adapted from psychology) in multivariate analysis, to denote a function of the observed variates, usually linear, which may be regarded as part of those variates; and hence as a "factor" of the variation, and (3) to denote a constituent item in an average or index-number.

FACTOR ANALYSIS. Suppose we have a multivariate sample of values $(x_1, x_2, \ldots x_k)$. We may be prepared to assume an underlying set of variables $z_1, z_2, \ldots z_p$, with $p < k$ such that each x is a linear function of the z's together with a part specific to itself,

$$x_i = a_{i1}z_1 + a_{i2}z_2 + \cdots + a_{ip}z_p + s_i$$

Factor analysis is the name given to the techniques for estimating the various parameters in a model of this kind. Many such techniques exist.

The z's are known as common factors, the s's as specific factors. If one of the z's contributes to all the x's, it is called a general factor, while one that contributes to some but not to others is called a group factor. The a's are called the factor loadings or saturations; a common factor with both positive and negative loadings is called bipolar. The proportion of the variance of a particular x accounted for by the common factors is called the communality of that x.

FACTORIAL. If n is a positive integer, factorial n means the product $1 \cdot 2 \cdot 3 \ldots n$. It may be denoted by the symbols $\underline{/n}$ or $n!$, but the latter form is generally preferred and the former seldom seen, except in older books. By convention, $0! = 1$. Generalization of such a product to include negative numbers or those that are not integers results in the gamma function.

See also **Binomial Series**.

FACTORIAL EXPERIMENT. A factorial experiment is one whose treatments are made up of combinations of the variants of several factors. The factor variants may be qualitative — e.g., crop varieties — or quantitative — e.g., amounts of fertilizer applied — but in either case are referred to as levels. Referring to the observations, for convenience as yields, any contrast between the mean yields for different levels of one factor, averaged over all levels of the other factors in the experiment, is said to belong to the main effect of the factor. The mean yields for all combinations of the levels of two different factors, averaged over all levels of the other factors, can be set out in a two-way table; a contrast between the entries in this table which is orthogonal to all the main effect contrasts is said to belong to the first order interaction between the two factors. Interactions of higher order are similarly defined.

The underlying notion behind the analysis into main effects and interactions is that of additivity of the effects of the different factors. If the effects are perfectly additive, all interactions are zero; the presence of first or higher order interactions discloses the presence of less or more complicated departures from additivity. In many fields of application, interactions involving 3 or more factors are often small enough to be neglected.

One of the most useful types of factorial experiment is that in which each factor has the same numbers of levels. An experiment with s factors each at p levels is called an s^p experiment, and each replicate will contain s^p treatments. In practice, p is often 2 or 3, but if several factors are to be investigated s^p may be large and heterogeneity of the experimental material may lead to loss of accuracy. To avoid this, each replicate may be laid down in a number of blocks in such a way that the contrasts between blocks coincide with treatment contrasts that are of little interest, such as the higher order interactions. This device is known as confounding.

If the true values of the high order interactions are zero, their estimates will provide estimates of experimental error. An experiment with many factors can then be carried out in a single replication, a suitable estimate of error still being available. Extending this notion, it is possible to carry out an experiment using only a suitably chosen fraction $1/g$ of all the possible treatment combinations. In this case it is found that the contrasts that can be estimated are sums of groups of g main effect and interaction contrasts; each member of such a group is called an alias of all the others. If it can be arranged that all the aliases of the contrasts that are of interest are high order interactions, the interpretation of the results remains reasonably unambiguous. Experiments with single or fractional replication enable a large number of factors to be investigated in a single experiment without the amount of experimental material reaching unmanageable proportions.

FACTOR OF SAFETY. The factor of safety is a number expressing the relation between the utmost endurance of a structural part, or of a complete structure, to the maximum actual demand that may ever be made upon it. But the factor of safety is not merely some ratio to allow for inaccuracies, lack of knowledge, or absence of confidence. Indeed, it has a very definite rational basis, which becomes more apparent as the conditions that govern the factor of safety become known. Factor of safety has many different forms, a few of which will be given below.

It includes a combination of the allowances necessary to be made in the use of practical data, including an allowance for the lack of precision with which certain stress conditions can be ascertained.

If the engineer could definitely specify the usage and the care to which his product would be put, a large element of the so-called factor of safety would not be necessary. It must include allowance for unavoidable shocks or jars that might be expected during the working life of the structure. The material used may not be homogeneous in character, or uniform in all deliveries. Then there is always the desire to be well on the safe side when, due to failure of some part, life will be endangered. Usually, the factor of safety is taken as the ratio of the ultimate strength claimed or accepted for the material, to the working stress used for design, and presumably reached under maximum design loading. When failure is measured by excessive deformation, the factor of safety might well be based on the elastic limit. Likewise, for elements subjected to repeated reversals of stress, the endurance limit should replace ultimate strength. In most old, well-organized fields of design, professional and standardizing societies have undertaken to specify working stresses for the commonly used materials, thus indirectly covering the factor of safety.

Factors of safety do not always bear this name; for example, the safety of a masonry dam against overturning is contained in a computed ratio of the overturning moment due to water pressure, divided by the stabilizing moment of the masonry weight. Safety in aircraft design is contained in a carefully and scientifically determined "load factor" made up in accordance with certain rules promulgated by a governmental bureau.

FACULAE. Large patches of bright material forming a veined network in the vicinity of sunspots. They appear to be more permanent than sunspots and are probably due to elevated clouds of luminous gas.

FADING (Communications). The fading of radio signals is inherent in the transmission of such signals and at best can only be partially compensated for in the receiver by automatic volume control circuits, diversity reception, etc. The compensation may often be made entirely satisfactory if the fading is of the simplest type, but if it is selective, compensation is not always satisfactory. Radio waves going out from the transmitter travel along various paths to the receiver, some of the waves travel along the ground, others are reflected from the ionosphere. In the broadcast band fading is usually caused by signals which have been reflected from the ionosphere combining vectorially with signals which have traveled along the earth (these are called respectively sky wave and ground wave). The sky wave does not return to the earth near the transmitter, so there is no fading in this region. And, at great distances from the transmitter, the ground wave has died out, so again there is no fading due to this cause. In the intermediate region, both waves may be present and there may be no fading if the phase of the two signals is such that they cancel fading results.

Since the ionosphere is continually changing, the phase of the reflected sky wave may cause cancellation at one instant and addition of the signals at the next. Different frequencies travel somewhat different paths in the ionosphere so the time to reach the receiver is different for the different sideband frequencies. Thus one frequency may reach the receiver to add

to the ground wave, while another may cancel. This produces what is known as selective fading and the output of the receiver is badly distorted. It should be realized that this is an effect of the transmission and not a characteristic of a given receiver. Both types of fading may be produced by two sky waves that have traveled different paths from the transmitter to the receiver. This is the cause of fading at the very high frequencies where the ground wave does not get far enough from the transmitter to cause any trouble.

FAGOT. In forging, a bundle of iron bars that will be heated and then hammered and welded to form a single bar.

FAHRENHEIT DEGREE. See **Temperature**.

FAHRENHEIT TEMPERATURE SCALE (abbr F). A temperature scale with the ice point at 32° and the boiling point of water at 212°. Conversion with the Celsius "centigrade" temperature scale (abbr C) is by the formula

$$F = 9/5\ C\ + 32$$

FAILURE (Structural). The inability of a structure or a structural member to perform its proper function causes a condition known as failure. This condition may be the result of sudden fracture as in the case of brittle materials or the excessive deformation of ductile materials. Another cause of failure is a lack of equilibrium between the external loads and resisting forces such as exists in structures that fail by sliding or overturning. Structures also may fail because of poor design. See also **Factor of Safety**.

FAINTING. See **Syncope**.

FAIR. With respect to weather, generally descriptive of pleasant weather conditions, with due regard for location and time of year. It is subject to popular misinterpretation, for it is a purely subjective description. When this term is used in weather forecasts (National Weather Service), it is meant to imply 1) no precipitation; 2) less than 0.4 sky cover of low clouds; 3) no other extreme conditions of cloudiness, visibility, or wind; 4) unrestricted visibility; and 5) light winds of generally less than 10 knots ($5\ m\ s^{-1}$).

FAIRING. An object is said to be faired if it is constructed to streamline shape, or has attached to it supplementary bodies which cause it to assume a shape of some degree of excellence of streamlining. The term has its major usefulness in aircraft nomenclature where many instances of fairing of parts in the exposed wind streams are present. Fairing of exposed struts, wheels, cabins, etc., does much to reduce wind drag and increase performance, although retraction of the landing gear eliminates the need of fairing or streamlining. Sometimes the part is actually built in a streamline shape. Sometimes the streamline shape is obtained by enclosing the part in a streamlined case, or by attaching to it a shaped piece of some light material, such as balsa wood. The best faired object in the subsonic region is one whose shape approaches that of a tear drop, having a ratio of length to width of approximately 3.5. For speeds above sonic, shapes other than the tear drop are being developed for better drag characteristics at high speeds.

FALCON *(Aves, Falconiformes).* Large birds of prey closely related to the hawks and eagles and like them in appearance. They are found throughout the world. One species of the Old World is called the windhover, *Falco tinnunculus*, or, in common with other species, kestrel. Another is the merlin, *F. aesalon*. The peregrine falcon, *F. peregrinus*, has been widely used for catching game and other birds. See Fig. 1.

Because of exposure to the pesticide DDT, by the 1960s the peregrine falcon became dangerously close to extinction. Although banning of DDT in North America stayed the demise of the bird, most of the them continue to be exposed to the chemical because of their wintering in South and Central America, where DDT has not yet been banned. The peregrine breeds on all continents except Antarctica. The birds produce a clutch of three eggs each year, hence, populations cannot increase at a rapid rate. The birds usually begin flying and hunting when only six weeks old.

A Peregrine Fund was established several years ago, and a number of scientists and falcon fanciers took extra measures to build the population back. Over 4000 peregrines have been released, and some 700 nesting pairs were known as of the summer of 1992. In some regions, the population is now self-sustaining. Specialists indicate, however, that the bird will continue to require assistance for some years. In 1975, the known existing pairs had reached the low total of 75 pairs.

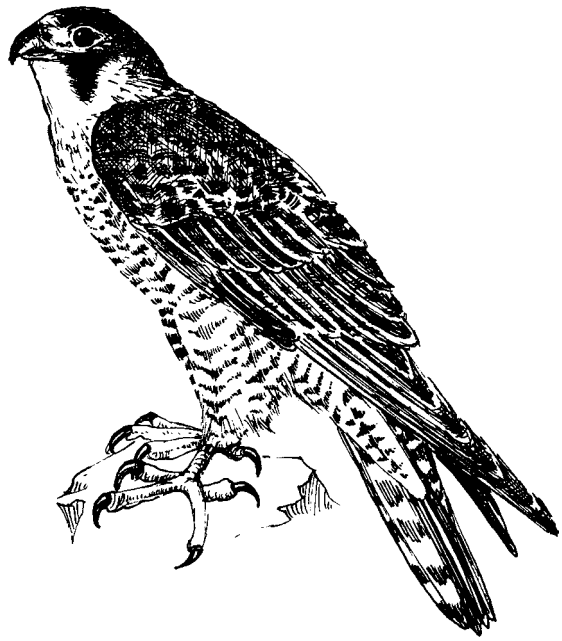

Fig. 1. A peregrine falcon (*Falconiformes peregrinus*) is a favorite of falconers. An adult peregrine can fly up to 60 miles (96 km) per hour in pursuit of prey. When on target, the falcon drops with folded wings up to a speed of 200 miles (321 km) per hour. Upon impact, the falcon's talons stun the prey, and often the falcon will circle back to recover the prey in mid-air.

Several species of falcons and merlins occur in North America, among them the duck hawk, *F. anatum*; pigeon hawk, *F. columbarius*; and the little sparrow hawk, *F. sparverius*. See also **Falconiformes**.

FALCONIFORMES *(Aves).* The ability to hunt prey is most highly developed in this order. These birds were also called birds of prey, which, however, is not a specific name since many birds of other orders also hunt for living prey. They are particularly distinguished by the "weapons" they use to overcome their prey. These include the short, hooked beak, with the upper mandible strongly curved, and in particular the strong feet with long toes, and the highly developed sharp claws, which are an excellent tool for grasping. By far the majority of falcons are adapted to capturing prey, which may be insects, amphibia, reptiles, small birds, or small mammals. A few species prefer a vegetarian diet.

Falconiformes (raptors) are easily distinguished from the members of other orders of birds. The body is strong, compact, and wide-breasted; the large head is generally rounded, and only rarely elongated. The neck is normally short and strong, and only seldom is it long. The rump is short, the breast and limb muscles are strong, and the short, hooked beak is laterally compressed. The cutting edges of the upper mandible project like scissors over those of the lower mandible. The foot is short, strong, with long toes, and an outer toe, which in some species can be rotated (to either the front or the rear). The claws are more or less bent. When they are strongly bent they are pointed and they form grasping tools for seizing prey.

There are 4 families: 1. The New World Vultures (*Cathartidae*); 2. the Secretary Birds (*Sagittariidae*); 3. Goshawks (*Accipitridae*); and 4. Falcons and related forms (*Falconidae*), with a total of 291 species. The distribution is worldwide.

In view of the extensive changes the natural environment has undergone at the hands of man, we have today a quite different understanding of the role of predators in their various habitats. From their relationship with other animals and in some cases, plants, it can be seen that they are not just "robbers," as assumed, but they play rather a definite role in the balance of nature. They remove animal corpses and feed to a great extent on sick or weak animals, thus ensuring that the population of their prey animals remains healthy and able to compete.

This applies particularly to the members of the two large families of the goshawks (*Accipitridae*) and the falcons (*Falconidae*). According to their abilities when seizing and killing prey, they may be divided into two

functional groups: (1) grasping killers, having a beak for tearing, hooking and cutting; and (2) grasping holders, having a beak for tearing, hooking, and biting. The first group includes most goshawks, the second, the pigmy and true falcons. The two groups are distinguishable not only by their beak structure, but also according to the structure and use of their feet, which have become converted into grasping tools.

The feet of grasping killers, as a rule, have short toes; only bird and bat hunters are an exception. The hind toe and the inner front toe have stronger or particularly strongly developed claws. The center claws and outer toes are clearly weaker, even among those birds that prey on small animals. These features are particularly evident on the feet of eagles and the goshawk. The feet of grasping holders, on the other hand, have claws that show no such differences in length. Only the claw of the hind toe is a little larger in these birds. The beaks of the grasping killers have sharp cutting edges on the sides of the upper mandible, as well as a tearing hook. With such beaks, they can cut into the tough skin even of larger animals. The beaks of the grasping holders, on the other hand, serve to split open the back of the prey's head, whereby the animal is held with the foot. In the falcons, the upper mandible has a "tooth" behind the hook that fits into an indentation of the lower mandible.

When prey has been seized and killed by the foot or by the bite of the beak into the back of the head, it is plucked more or less carefully, if it is a bird or mammal. From insects, the coarse pieces of chitin, such as the wing covers of beetles are removed. Nevertheless, much indigestible material, such as feathers, hairs, or pieces of chitin, is consumed with the morsels of food. The food is predigested in the crop by gastric juice which is "pumped up," and is then squeezed into the stomach, which dissolves everything that is digestible. Feathers and hair are gathered into clumps and are regurgitated through the beak as "pellets," generally after 16–18 hours.

All raptors of the functional group of grasping killers, with tearing, hooking, and cutting beaks, build their own nests. Nests may be on the ground, but are usually found on trees. They may be newly built, or the birds may utilize old nests of other raptors or even of crows and ravens as a base. In contrast, the grasping holders with tearing, hooking, and biting beaks use ready-made platforms, namely ledges on cliffs or old nests in trees.

The territories occupied by individual pairs of raptors during the breeding season are divided into the hunting area and the nest area. This division, as well as the size of the hunting and nest areas, offers a good insight into the function of the two. The hunting area of hunters of very small animals is small, becoming larger with the size of the prey of the raptor species. Some, like the migrants among the raptors, hunt over several continents. Others, like the goshawk and sparrow hawk, do not hunt near the nests during the breeding season. Only actions directly related to the nest and the young are performed in it, such as the preparation and distribution of the prey. Hunting is clearly separated from care of the eggs and young. In species that often breed socially, hunting and nesting areas cannot be separated.

The role of predators in the population of other inhabitants of their environments has nothing at all to do with our concepts of usefulness or harmfulness. Rather, the predator has an extraordinary significance with the maintenance of the balance of nature. See also **Caracara**; **Condor**; **Eagle**; **Falcon**; **Hawk**; and **Vulture**.

FALLOPIAN TUBES. See **Gonads**.

FALLOUT (Radioactive). The term *fallout* generally has been used to refer to particulate matter that is thrown into the atmosphere by a nuclear process of short time duration. Primary examples are nuclear weapon debris and effluents from a nuclear reactor excursion. The name fallout is applied both to matter that is aloft and to matter that has been deposited on the surface of the earth. Depending on the conditions of formation, this material ranges in texture from an aerosol to granules of considerable size. The aerodynamic principles governing its deposition are the same as for any other material of comparable physical nature that is thrown into the air, such as volcanic ash or particles from chimneys. Therefore, many of the principles learned in studies of fallout from nuclear weapons can be applied to studies of other particulate pollution in the atmosphere.

The topographic distribution of fallout is divided into three categories called: (1) local (or close-in); (2) tropospheric (or intermediate); and (3) stratospheric (or worldwide) fallout. No distinct boundaries exist between these categories. The distinction between local and tropospheric fallout is a function of distance from source to point of deposit. The primary distinction between tropospheric and stratospheric fallout is the place of injection of the debris into the atmosphere, above or below the tropopause. Whether the radioactive debris from a nuclear weapon becomes tropospheric or stratospheric fallout depends on yield, height, and latitude of burst (the height of the tropopause is a function of latitude).

Because air acts as a viscous medium, a drag force is developed to oppose the gravitational force that acts on airborne particulate matter. This makes the velocity of fall dependent on particle size. The larger particles (diameters greater than about 20 micrometers) have a higher rate of settling and create local fallout. Smaller particles injected below the tropopause are carried by prevailing winds over large regions of the surface of the earth, and they create the tropospheric fallout. Tropospheric fallout particles larger than about 0.1 micrometer diameter continually mix through the circulating air mass that is in contact with the surface of the earth and gradually settle to the ground, or are washed down by rain or snow. Many smaller particles form nuclei for raindrops. Parts of the tropospheric fallout may remain in the atmosphere for a month or more, long enough to circle the earth several times. The mean residence time above the tropopause of stratospheric fallout is from 5 to 30 months, during which time it completely encircles the earth. It gradually returns through the tropopause, primarily in certain regions where mixing between the two layers is more probable.

The exact characteristics of the radiation associated with fallout depend on the nature of the nuclear processes from which its radioactivity originates. Generally, these radioactive nuclides are products formed from the fission of uranium or plutonium, but, under appropriate circumstances, considerable quantities of radioactivity can be formed through nuclear reactions induced by neutrons that are produced by the weapon or reactor. The radiation problems associated with local fallout are usually those of high-intensity gamma-ray radiation fields resulting from the relatively large quantities of radioactive material that fall back to earth within a few tens of miles from the point of origin. The important radioactive materials consist in this case of short-lived fission products and neutron-induced radioactive nuclides. The hazards of worldwide fallout come more from the problems of the long-lived radionuclides, such as ^{134}Cs, ^{137}Cs, and ^{90}Sr, that can enter the human food chain and ultimately be absorbed by the body.

For a nuclear weapon burst in air, all materials in the fireball are vaporized. Condensation of fission products and other bomb materials is then governed by the saturation vapor pressures of the most abundant constituents. Primary debris can combine with naturally-occurring aerosols, and almost all of the fallout becomes tropospheric or stratospheric. If the weapon detonation takes place within a few hundred feet of (either above or below) a land or water surface, large quantities of surface materials are drawn up or thrown into the air above the place of detonation. Condensation of radioactive nuclides in this material then leads to considerable quantities of local fallout, but some of the radioactivity still goes into tropospheric and stratospheric fallout. If the burst occurs sufficiently far underground, the surface is not broken and no fallout results.

FALSE ACACIA. See **Acacia Trees**.

FALSE CLEAVAGE. This is also called strain-slip cleavage by the British geologists. It differs from the typical slaty cleavage in that it is obviously associated with incipient foliation of metamorphic rocks.

FALSE CYPRESS. See **Cypress Trees**.

FALTUNG. See **Convolution**.

FAN. When large volumes of gas, usually air, must be moved with practically no compression (pressure rise of 1 psi or less), the device used is termed a fan (as contrasted with compressor). Centrifugal fans fulfill a variety of needs, such as ventilating, heating, combustion draft, and drying applications.

In contrast to the high-pressure centrifugal compressor, the fan has narrow blades and very little compression occurring in the blading. However, the blade action on the gas is to increase its speed, thus requiring a diffusion to gain pressure. This diffusion is accomplished in a scroll case surrounding the wheel and comprising the casing of the fan. Diffuser guide vanes may sometimes be inserted in the scroll case to improve efficiency by reducing turbulence. Simple radial balding is sometimes used due to its cheapness and simplicity, but most fans have blading that is curved. Figure 1 shows the appearance of wheels incorporating in the one case forwardly, and in the other, backward curved blading. Vector diagrams show that for the same relative velocity of the gas leaving the wheel and the same wheel speed, the absolute velocity is greater with forwardly curved blades. Achievement of efficient diffusion is therefore more important with forwardly curved blades and pressure increase is greater. Conversely for the same pressure increase, forwardly curved blading may operate at lower rim speeds. However, backward curved blading can be built so that somewhere near the best operating point (maximum efficiency) pressure rise diminishes more rapidly than volume increase and thereby induces a self-limiting feature in power consumption that is desirable in many applications. Power demand continues to increase with discharge in forwardly curved blading until well past the best operating point.

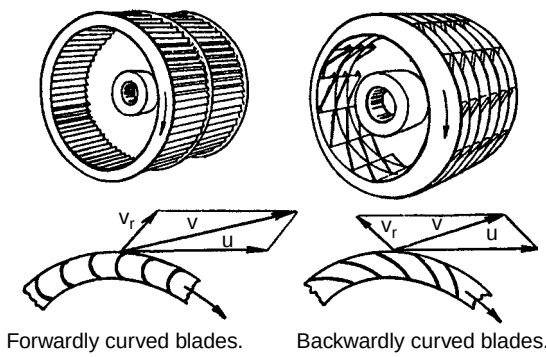

Fig. 1. Fan wheels, showing blading.

Since the pressure increments are small, an excellent approximation, which simplifies the energy relation, is to assume a constant volume flow through the fan. Given the weight of gas flowing per minute, W, and the draft, D (expressed in feet of air), the power imparted to the air is:

$$\text{air horsepower} = \frac{WD}{33{,}000}$$

Given the volume delivered per minute, V (in cubic feet), and dynamic pressure, P (pounds per square foot), power is also:

$$\text{air horsepower} = \frac{PV}{33{,}000}$$

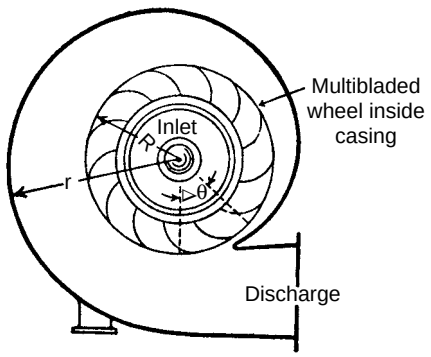

Fig. 2. Centrifugal fan. Typically $r = R\left(1 + \left(\frac{\theta^\circ}{360}\right)\right)$.

The mechanical efficiency of a fan is the ratio of one of the above theoretical powers to the required drive power. Multivane centrifugal fans (Fig. 2) will usually exhibit an efficiency of from 70 to 80% at their optimum point, with radial plate type fans being somewhat poorer in performance.

Fan Characteristics. This is a curve showing the relation between pressure and delivery. It is important because a fan operates at the conditions depicted by the characteristic curve. Hence, it is a basis for fan selection. The characteristic is determined by the shape of the blades. Blades curved forward in the direction of rotation have what is known as a rising characteristic — pressure increases with volume delivered. This characteristic is productive of low tip speed but fans having it can overload their drives if ignorantly handled. Backward curved blades have a drooping characteristic.

The centrifugal fan compresses the air or gas but slightly. In modern fan theory the work of compression is neglected and the action is assumed to be similar to a reversed hydraulic turbine or a centrifugal pump.

Ventilating Fan. Fans in this service are used to move air in predetermined directions for changing the air in buildings, removing air charged with offensive odors and dangerous contaminants, furnishing air to tunnels and mines. Ventilating fans are commonly fixed in position and connected to duct systems on the inlet or discharge sides, or both. Propeller fans have a limited use in this field. Ventilating fans usually are centrifugal because the application often requires overcoming considerable static pressure.

Draft Fan. These fans are used to supplement or supersede chimney action in the production of draft — hence find applications in large furnace, boiler, and other combustion systems, and frequently in cooling tower applications. In application, fans may be used as forced draft or induced draft fans. In a forced-draft application, the fan pushes the air past a finned air cooler, for example; the induced-draft fan pulls the air past the cooler. Draft fans are designated as plate (paddle wheel), multivane, or propeller type, the latter seldom used for this type of service. The plate fan is employed to some extent, but the multivane centrifugal fan is the most common type. Backward curved blade wheels are usually selected for forced draft service. This is because of the high speed, suitable for direct motor drive, the self-limiting power demand (a necessary feature when two or more fans are operated in parallel), and high static efficiency. Induced draft fans handle hot chimney gas. Forwardly curved blades which develop a given draft at lower speeds than those with backward curvature are frequently chosen for this service, since the speeds and the centrifugal stresses in the wheels will be least.

Propeller Fan. These fans operate with air flow parallel to the axis of rotation of the fan. Generally, these fans may be grouped into (1) fans with thin sheet blades of metal or composition material or even flexible material and (2) fans with blades of airfoil section. Examples of the first class are the table fans, small ventilating fans, ceiling fans, unit heater fans, and radiator cooling fans. With the exception of certain low−speed ceiling fans, these are characterized by high rotative speed and low efficiency. The blades are often stamped in a single piece from a sheet of metal, then twisted slightly and mounted on the motor shaft. These fans are employed to move air but are not satisfactory if the air is to be forced against any pressure increment. The second class of propeller fans reflects a more scientific application of the axial flow principle. Whereas the first class moves the air largely by impulse against the face of the fan blades, the airfoil sections of the latter class perform in accordance with airfoil theory of lift. While more expensive, they are also more efficient, although the latter advantage is gained in sizes more suitable to industrial than domestic usage. The axial flow fan can move large volumes against light static pressures and is frequently both more compact and more readily applied than the centrifugal type.

FANGLOMERATE. The term proposed by Lawson in 1913 for a conglomerate composed of the coarser clastic sediments deposited at the head of alluvial fans.

FANNING BEAM. A radiant energy beam, as a radar beam, which sweeps back and forth over a limited arc.

FARAD. See **Units and Standards**.

FARADAY DARK SPACE. This term denotes the nonluminous region between the negative glow and the positive column in a gas-discharge tube (Crookes tube) at moderate pressure.

FARADAY DISK MACHINE. This device consists essentially of a copper disk, rotated so that it "cuts" the flux between the poles of an electromagnet and serves as a low voltage D.C. generator by virtue of the induced, radial electromotive force. One output brush contacts the axle; the other, the rim beyond the magnet pole-gap. It is a form of the homopolar generator.

FARADAY EFFECT. See **Magneto-Optical Rotation**.

FARADAY LAW OF ELECTROMAGENTIC INDUCTION. The electromotive force induced in a circuit is

$$E = \oint_l E \cos\theta dl = -\frac{d\phi_m}{dt}$$

where $\oint_l E\cos\theta dl$ is the line integral of the electric field intensity around a closed path and $d\phi_m/dt$ is the rate of change with time of the magnetic flux through the area enclosed by the path. The electromotive force is given in volts and the magnetic flux, in webers.

FARADAY, MICHAEL (1791–1867). Faraday was an English physicist. After hearing Sir Humphrey Davy, professor of chemistry, at the Royal Institution speak, Faraday sought a job with Davy as his assistant, and thus his scientific career began in chemistry and electricity.

Faraday is credited with discovering electrical rotation caused by magnetism and making in 1821 the first electric motor. Later, Faraday also discovered electromagnetic induction and invented the transformer. His work led to the growth of electrical technology.

J. M. I.

FAR POINT OF THE EYE. This term designates the nearest point on which the eye is focused when fully relaxed.

FARR, WILLIAM (1807–1883). The son of humble parents, Farr was born in Shropshire, and early adopted by Joseph Pryce of Dorrington near Shrewsbury. Initially self-educated, he later studied medicine at the Salop Infirmary and with a local practitioner before completing his training in Paris and at University College London. He obtained the Licenciate of the Society of Apothecaries in March 1832, and in 1833 began a private practice in Fitzroy Square, London. He was twice married, and fathered eight children. In a competitive medical market, Farr's practice struggled, and for some years he supplemented his income by medical journalism. His early writings reveal a deep interest in hygiene as a means of social reform, and his gradual realization that vital statistics constituted an important tool of public health reform. By the mid-1830s, he had become a recognized expert on government health statistics, and in 1839 he joined the staff of the General Register Office (GRO). He made the rest of his career at the GRO, retiring in 1879.

Farr's impact on contemporary social and public health reform was largely due to his annual analyses of the birth, marriage, death and, in particular, cause of death, data collected by the GRO. These analyses covered subjects as diverse as occupational mortality, the contrasts between urban and rural death rates, and epidemic theory. His work contributed to the development of a number of fields, including demography, actuarial science, public health and epidemiology. A selection of his writings entitled *Vital Statistics* was published posthumously in 1885.

FARSIGHTEDNESS. See **Vision and the Eye**.

FAR ULTRAVIOLET SPECTROSCOPIC EXPLORER (FUSE) MISSION. See **Explorers Program**; and **Space Science Missions: Universe**.

FASCIA. 1. Layers of connective tissue composed largely of regularly arranged fibers. They cover muscles.

2. Marks in the form of bands.

FAST FOURIER TRANSFORM (FFT). An algorithm to compute rapidly the digital form of the discrete Fourier transform. The procedure requires that the length of the data series undergoing transformation be an integral power of two, which is often achieved by truncating the series or extending it with zeros. More flexible mixed-radix algorithms have been developed that allow data series of any length. They gain efficiency as the prime factors of the length become small, and they are equivalent to the FFT when the data series length is a power of two.

See also **Fourier Transform**.

FAT. A glyceryl ester of higher fatty acids such as stearic and palmitic. Such esters and their mixtures are solids at room temperature and exhibit crystalline structure. Lard and tallow are examples. There is no chemical difference between a fat and an oil, the only distinction being that fats are solid at room temperature and oils are liquid. The term fat usually refers to triglycerides specifically, whereas lipid is all-inclusive.

See also **Lipids**.

FATA BROMOSA. An apparent fog in the distance where no fog actually exists. The appearance is sufficiently compelling that one can observe ships, say, vanishing into or emerging from the seeming fog. The fata bromosa seems to be an infrequent partner of the superior mirage. The name translates as "fairy fog." See also **Mirage**.

AMS

FATA MORGANA. A mirage, but the specific physical circumstances under which fata morgana should be applied to a particular sighting are ill-defined. The best that can be said is that the mirage interacts with features in the landscape to present a scene of sufficient ambiguity that viewers often arrive at quite fanciful interpretations. Cases reported include those of the apparent sighting of cities, mountains, forests, or islands (sometimes metamorphosing one into the other) in places where it was known that no such things existed. Indeed, the mirage's eponym is the fairy Morgan, the legendary half-sister of King Arthur, whose magical powers enabled her to create castles in the air ("fata" is Italian for "fairy"). It is not that any particular occurrence is the least bit mysterious or that either the meteorological or optical behavior is difficult to understand. Indeed, most cases of the fata morgana are undoubtedly multiple-image superior mirages, sometimes with marked magnification, sometimes complicated by periodic inhomogeneities, sometimes augmented by an inferior mirage. See also **Mirage**.

AMS

FATHOM. The common unit of depth in the ocean, equal to six feet (1.8 meters).

It is also sometimes used in expressing horizontal distances, in which case 100 fathoms (600 feet) is equivalent to one cable or very nearly to one-tenth of a nautical mile (185.2 meters (607.6 feet).

FATIGUE CORROSION. See **Corrosion Fatigue**

FAT METABOLISM. See **Lipidoses**.

FATIGUE (Metals). Failure of metal parts by progressive cracking caused by repeated application of stress. Most fatigue failures start at the surface where discontinuities in section such as square shoulders, screw threads, or even tool marks cause a high concentration of stress.

Internal discontinuities may also start a fatigue crack. The most notable example is "transverse fissures" in rails, which are believed to originate in areas within the rail section known as "flakes," a defect originating during the cooling period after hot rolling. Once a minute crack is started anywhere in the section, the root of the crack becomes the seat of high stress concentration upon subsequent applications of tensile stress. Thus, the crack will spread until the section is too weak to carry the load and the remaining portion will fracture suddenly.

The portion of the section that failed progressively will be worn quite smooth due to the rubbing action of successive stress applications (e.g., alternate tension and compression in a rotating member loaded as a beam). The suddenly fractured portion will have the usual crystalline appearance characteristic of fractures in heat-treated steels. For this or other reasons, fatigue failures have wrongly been blamed on "crystallization" of the metal.

All metals are crystalline and no alteration in the size or shape of the grains or crystals takes place in service during or before fatigue failure. (Exceptions might be made in the case of lead and other alloys which recrystallize when cold worked at room temperature.)

The fatigue strength, also called endurance limit, is the maximum stress that can be applied repeatedly without failure. In the case of steel, tests are run at a given maximum stress to 10,000,000 reversals or cycles of stress unless failure occurs earlier. It has been found that failures do not occur in steels after a successful run of this duration (4 days at 1700 rpm or less than 1 day at 10,000 rpm). In the case of aluminum alloys and certain other non-ferrous metals, fatigue, failures have occurred after much longer runs, hence tests are sometimes made to 500,000,000 cycles. The materials do not have a true endurance limit; and the number of reversals of stress is stated in reporting the fatigue strength.

The most common test is a rotating beam type in which a carefully machined and polished sample is loaded as a beam while rotating in anti-friction bearings. As any point in the periphery rotates from top to bottom to top position the stress changes from maximum compression to maximum tension and back to maximum compression. From 4 to 8 or more individual tests at various maximum stress levels may be required to determine the endurance limit.

The endurance limit for smooth test specimens run in normal atmospheres at room temperature is an ideal or limiting value. In the case of steels not hardened, or heat-treated to moderate hardness, the smooth specimen endurance limit is approximately one-half of the tensile strength. The endurance limit-tensile strength ratio is less than one-half for many other materials.

The presence of stress raisers, particularly at the surface, will lower the endurance limit. Notch sensitivity can be evaluated as the ratio of the endurance limit of a standardized notched specimen to that of a smooth specimen. Fatigue tests run in a corrosive medium, either gaseous or liquid, generally give much lower endurance limits than tests run in normal atmosphere. Corrosion-fatigue is responsible for many service failures of shafts and other stressed parts of pumps, engines, or processing equipment operating in corrosive media. Protective coatings are sometimes used to improve service life. Nitriding of alloy steel parts has proved very effective.

In order to guard against fatigue failures in critical parts such as connecting rods, they should be fabricated from high-quality steels using designs that avoid regions of stress concentration such as sharp fillets and engraved part numbers. They should be finished over all, avoiding tool or grinding marks. As a further aid in obtaining high fatigue strength such parts are being surface peened by a shot blasting process which work-hardens the surface and sets up compressive stresses in the surface layers. This raises the endurance limit, apparently by reducing the maximum tensile stresses that can be developed at the surface in normal operation.

FATS AND OILS. See **Diet**.

FATTY ACIDS. A carboxylic acid derived from or contained in an animal or vegetable fat or oil. They are non-toxic and readily biodegradable. All fatty acids are composed of a chain of alkyl groups containing from 4 to 22 carbon atoms (usually an even number) and characterized by a terminal carboxyl group −COOH. The generic formula for mentioned acetic is $CH_3(CH_2)_xCOOH$ (the carbon atom count includes the carboxyl group). Fatty acids may be saturated or unsaturated (olefinic), and solid, semisolid, or liquid. They are classed among the lipids, together with soap and waxes. See also **Carboxylic Acids**; and **Lipids**.

Saturated Fatty Acids

A fatty acid in which the carbon atoms of the alkyl chain are connected by single bonds. The most important of these are butyric (C_4), lauric (C_{12}), palmitic (C_{16}), and stearic (C_{18}). Stearic acid leads all other fatty acids in industrial use, primarily as a dispersing agent and accelerator activator in rubber products and soaps. See also **Stearic Acid and Stearates**.

Unsaturated Fatty Acids

A fatty acid in which there are one or more double bonds between the carbon atoms in the alkyl chain. These acids are usually vegetable derived and consist of alkyl chains containing 18 or more carbon atoms with the characteristic end group −COOH. Most vegetable oils are mixtures of several fatty acids or their glycerides; the unsaturation accounts for the broad chemical utility of these substances, especially of drying oils. See also **Vegetable Oils (Edible)**. The most common unsaturated acids are oleic, linoleic, and linolenic (all C_{18}). Safflower oil is high in linoleic acid, peanut oil contains 21% linoleic acid, olive oil is 38% oleic acid, palmitoleic acid is abundant in fish oils. Aromatic fatty acids are now available. See also **Chlorinated Organics**; **Linoleic Acid**; **Linolenic Acid**; and **Oleic Acid**.

Note: Linoleic, linolenic, and arachidonic acids are called essential fatty acids by biochemists because such acids are necessary nutrients that are not synthesized in the animal body.

Uses

Special soaps, heavy-metal soap, lubricants, paints and lacquers (drying oils), candles, salad oil, shortening, synthetic detergents, cosmetics, and emulsifiers.

For further details, refer to Fatty Acid Producers Council, 475 Park Ave. S., New York, NY, 10016.

See also **Carboxylic Acids**; and **Chlorinated Organics**.

FATTY ALCOHOL. A primary alcohol (from C_8 to C_{20}), usually straight chain. High molecular weight alcohols are produced synthetically by the Oxo and Ziegler processes. See also **Oxo Process**. Those from C_8 to C_{11} are oily liquids; those greater than C_{11} are solids. Other methods of production are (1) reduction of vegetable seed oils and their fatty acids with sodium, (2) catalytic hydrogenation at elevated temperatures and pressures, and (3) hydrolysis of spermaceti and sperm oil by saponification and vacuum fractional distillation. See also **Saponification**; and **Soaps**. The more important commercial saturated alcohols are octyl, decyl, lauryl, myristyl, cetyl, and stearyl. The commercially important unsaturated alcohols, such as oleyl, linoleyl, and lynolenyl, are also normally included in this group. The odor tends to disappear as the chain length increases.

Uses include: solvent for fats, waxes, gums, and resins; pharmaceutical salves and lotions; lubricating-oil additives; detergents and emulsifiers; textile antistatic and finishing agents; plasticizers; nonionic surfactants and cosmetics.

See also **Detergents**; and **Plasticizers**.

FATTY AMINE. A normal aliphatic amine derived from fats and oils. May be saturated or unsaturated, and primary, secondary, or tetiary, but the alkyl groups are straight chain and have an even number of carbons in each. The length varies from 8 to 22 carbon atoms.

FATTY ESTER. A fatty acid with the active hydrogen replaced by the alkyl group of a monohydric alcohol. The esterification of a fatty acid, RCOOH, by and alcohol, R'OH, yields the fatty ester RCOOR'. The most common alcohol used is methanol, yielding the methyl ester $RCOOCH_3$. The methyl esters of fatty acids have higher vapor pressures than the corresponding acids and are distilled more easily.

FAULT. See **Earth Tectonics and Earthquakes**.

FAUNA. The animal population of a region.

FAX PROFILE (FAX). See **Bluetooth™ Wireless Technology**.

F-DISPLAY. In radar, a rectangular display in which a target appears as a centralized blip when the radar antenna is aimed at it. Horizontal and vertical aiming errors are respectively indicated by the horizontal and vertical displacement of the blip. Also called *F-scan, F-scope*, or *F-indicator*.

FEATHERBACKS *(Osteichthyes).* Of the order *Isospondyli* and family *Notopteridae*, the featherback is of peculiar form and found in Africa and the Oriental region. They are characterized by a very long anal fin, extending nearly the full length of the fish on its undersurface to the tip of the tail, thus masking the presence of a tail fin. The dorsal fin is slender, delicate, feather-like. Hence the name of this fish. The rippling action of the long anal fin provides the propulsion and the feathery dorsal fin serves as the rudder. Featherbacks are a freshwater fish and comprise four species. They are highly regarded as food fishes. *Notopterus chitala*, the largest of the species, attains a length of about 3 feet (0.9 meter) and is found in the waters of India and Australia. Spawning of featherbacks in eastern nations has been encouraged because of their demand as a food fish. A somewhat smaller species (*N. notopterus*) occurs in the same geographic regions. The species *Notopterus afer* and the so-called false featherfin (*Xenomystis nigri*) both are found in West Africa. The latter is a small fish of about 6 inches (15 centimeters) in length, and sometimes is selected for aquariums.

FEATHERING (Aircraft). An object of flat plate shape in a fluid stream has maximum resistance to relative motion if its largest area is placed in an attitude perpendicular to the fluid stream, and minimum when the smallest area is so placed. Conditions occasionally arise when it is desirable to have a maximum resistance at one point of a cycle of events, and minimum at another. For example, during the cycle of a rowing stroke, the blade of the oar should have maximum resistance to motion in the water, whereas during the return stroke it should have minimum air resistance. Certain experimental types of lifting planes or airfoils have been built involving this same action. Some helicopters use the feathering action, often in conjunction with flapping of the blades, to equalize the lift on advancing and retreating blades. The act of first presenting the surface of maximum resistance, followed by the surface of minimum resistance on a return stroke, is known as feathering. Controllable pitch propellers have been equipped with hub mechanisms and controls to permit the pilot to feather the blades when the engine was either throttled or inoperative. This action assists control and performance of multi-engined aircraft having one or more engines inoperative; it also allows a single-engined airplane to reach higher terminal diving speeds. Feathering the propeller will keep a damaged engine from "windmilling" and increasing the damage; moreover, the resistance of a feathered propeller is far less than that of a windmilling propeller. Feathering is also applied to the change in the angle of setting of the blades of a helicopter either to secure control or to equalize lift on the advancing and retreating sides. See also **Airplane**; and **Helicopters and V/STOL Craft**.

FEBRILE. Characterized by fever.

FECHNER COLORS. Visual sensations of color induced by intermittent achromatic stimuli (white light).

FECHNER FRACTION. If the eye can just distinguish an object whose brightness differs by an amount dB from a large field of brightness B, the contrast sensitivity may be measured by dB/B, sometimes called the Fechner fraction.

FEEDBACK. Systems in general have a direction of signal flow, which can be called the principal transmission path. The direction from input to output of any amplifying component is an example of this idea. If in addition to the primary transmission path, there exists one or more paths which allow signals to flow in the opposite direction and which are joined to the primary path at each end, then a feedback system exists. Feedback is the transfer of energy from the output to the input of a system, or from one part of a system to another in a direction opposite to the main flow of energy. This concept is illustrated in Fig. 1, which gives the block diagram of a feedback amplifier with a main transmission path having a gain A and a transmission path from output back to the input which has a gain β.

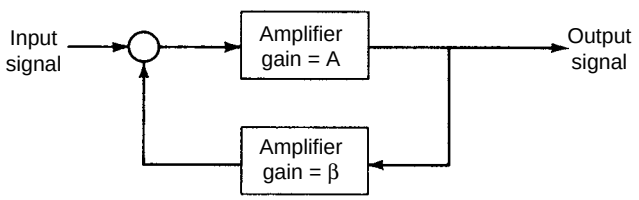

Fig. 1. Single-loop feedback system.

Figure 1 illustrates the essential elements of a feedback system. They are: an input, an output, a transmission path that develops some measure of the output signal, a device that permits the comparison of the input signal and measure of the output signal in order to develop a so-called error signal, and a device or devices in which the error signal is converted to the desired output signal. The feedback system, when viewed in these terms, attempts to make the measure of the output equal to the input signal. Servomechanisms and regulators are typical examples of feedback systems.

It is evident from Fig. 1 that a complete transmission path or feedback loop is formed by the combination of the forward and backward paths essential for feedback to exist. A system having only one feedback loop is called a single-loop system, whereas systems having more than one loop are called multiple-loop systems. Figure 2 shows a block diagram of one such system.

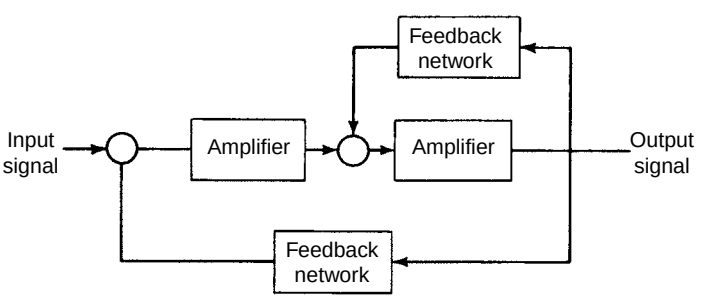

Fig. 2. Multiple-loop feedback system.

In practice, there are many systems that may be classified as feedback systems, due to their dependence of one quantity upon another occurring at some later point in the casual chain. In general, however, the more important class of feedback systems are those in which the feedback loop contains an active element as shown in Figs. 1 and 2. It is to such systems that feedback theory is mainly applied. It is also only such systems that are

capable of sustained oscillations or instability, a property that distinguishes them from purely passive systems or systems including active elements which are not included in feedback loops.

This last statement is, however, only applicable to what might be called engineering systems. Feedback theory has been applied with some measure of success to other fields, notably economics and ecology. It is known that economic systems are liable to sustained oscillations (the so-called booms and slumps) as also are, for instance, the population densities of certain interacting animal species (e.g., lynxes and foxes). The active elements in these systems, however, are often difficult to assess.

The main reasons for introducing feedback into a system are as follows. (1) To modify the gain-frequency characteristics of a system; this includes, for instance, modifying the degree of stability of the system, modifying its cutoff frequency, making the gain more uniform over the working band of frequencies, etc. (2) To minimize the effects of nonlinearities of a system. (3) To minimize the effects of the variation of system parameters. (4) To minimize the output noise level of a system. (5) To modify, particularly in feedback amplifiers, the input and output impedances of the amplifier. (6) To limit the amplitude of one or more system quantities, e.g., torque in an electromechanical control system.

Associated with any feedback loop is the gain of the transmission system that constitutes the loop. This gain is called the *loop gain*. The negative value of the gain is spoken of as the *return ratio*. In the system considered in the first figure, the loop gain is $A\beta$ and the return ratio is $-A\beta$. A quantity of fundamentally important quantity in feedback systems is one called the *return difference*, which is defined as unity plus the return ratio. For the system considered earlier, the return difference is $1 - A\beta$. For single-loop systems, of which Fig. 1 is representative, the return difference $1 - A\beta$ profoundly affects the system characteristics. The gain of the complete system relative to the gain of the amplifier (gain A) will be increased if $|1 - A\beta| < 1$. The feedback is then spoken of as positive or regenerative. On the other hand, the system gain will be less than A if $|1 - A\beta| < 1$. This condition is referred to as one of inverse feedback (negative or degenerative).

When negative feedback is employed, the system with feedback is found to possess improved characteristics relative to the nonfeedback version in direct proportion to the magnitude of the return difference. Stability of gain change as a result of system parameters, reduction of harmonic distortion and extraneous signals introduced in output stages, and improved frequency response (lower distortion) are among the benefits resulting from the use of negative feedback. Since the overall system gain is inversely proportional to the value of return difference attained, it is seen that the benefits are obtained at the price of a reduction in gain. In many practical applications, the potential benefits far outweigh their cost.

There are situations where the use of positive feedback or regeneration is advantageous. This is particularly true in amplifier applications where the gain of an amplifier can be increased so that the output signal obtained with a prescribed constant input signal is far in excess of that obtainable from the same amplifier without the feedback. The **Q** of the tuned circuit used in an amplifier stage may be increased materially by the use of regenerative feedback. If the amount of positive feedback oscillator, a device which furnishes an output signal without need for an input.

Inasmuch as feedback amplifiers and feedback oscillators have the same structural form, it is important to have a basis for determining the behavior in this condition of a specific structure. Whether a given feedback amplifier acts as an oscillator or as a well-behaved amplifier is a function of the transient response of the device. To act as an oscillator it must have transient response terms, which increase with time when power is first applied. For an amplifier to be classed as stable, on the other hand, the initial transients must decay with time. One simple test for stability against oscillation is known as the Nyquist criterion. The test may be used not only for amplifiers, but for any single- or multiple-loop feedback system. In its simplest form, which applies to single-loop systems only, it states: Plot the imaginary component of the complex number representing the loop gain $A\beta$ frequency (0 to ∞). If the resulting curve encloses or passes through the point -1, the system will oscillate. If the point is not closed, the system will be stable. This criterion is easy to employ, using laboratory measurements, and it finds considerable practical application.

FEEDBACK AMPLIFIER. See **Amplifier**.

FEEDBACK CONTROL. A basic form of automatic control action in which a measured variable is compared with its desired value to produce an actuating error signal which is acted upon in such a way as to reduce the magnitude of the error. See Fig. 1 for a simple feedback control system. See also **Feedback**; and **Signal (Instrument)**.

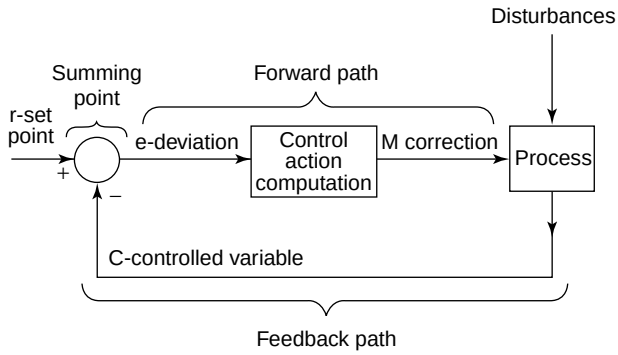

Fig. 1. Fundamental elements of feedback control: r = set point; c = controlled variable; e = error or deviation; M = manipulated variable.

A feedback loop or *closed loop* is a signal path which includes a forward path, a feedback path, and a summing point, and which forms a closed circuit. Because of the recirculation or feedback, the control action computation, which determines the corrective action required to maintain the measured variable at the setpoint, is critical to avoid cycling and instability. Where the feedback is positive, i.e., in phase with the deviation, the error is magnified and the process cannot be controlled. Only when negative feedback is present can the deviation be reduced. A reversal of phase must occur at the summing point in order that the effect of e (the control input) is opposite to that of c (the controlled variable). All feedback controllers produce a phase shift of 180° to give a negative feedback.

Feedback control is fundamental to closed-loop controllers. There are several forms of control action that embrace this principle. See also **Control Action**.

By contrast, an open loop or *open-loop control* may be defined as a single path without feedback. For example, a process or machine that is preprogrammed to function on a time basis and does not take into consideration continuous measurements of the end results as a criterion for adjusting the control system is open loop. In such a system, no information is fed back to alter the action of the controller.

FEEDBACK (Hormonal System). See **Endocrine System**; and **Hormones**.

FEEDER (Gravimetric). Frequently in the form of belt scales, the function of a gravimetric feeder is to continuously weigh material as it leaves a hopper, chute, or bin while in transport to a process. The gravimetric feeder delivers a desired amount of material within a given time period and, in this sense, are solid mass flowmeters, the setpoint (desired rate) of which can be adjusted by the operator. Some situations require adding a small quantity of additive material to an uncontrolled flow of bulk material. A belt scale may be used to measure the "wild flow" stream whose rate signal feeds the ratio input circuit of a setpoint controller which incorporates a ratio adjustment that establishes the ratio of additive to wild flow. An increase or decrease in the wild flow rate produces a corresponding change in the additive flow rate of the feeder, thereby maintaining the correct proportion. More than one additive may be involved in such a system. The wild flow may be of a solid or a liquid; the additive materials may be solids or liquids.

The use of gravimetric feeders in a multiunit proportioning system involving the simultaneous blending of three bulk materials is shown in Fig. 1. The system incorporates a master control that permits increasing or decreasing the total flow rate of the system. This may be accomplished in several ways: (1) A manually adjusted power supply that provides a master reference signal to feed the setpoint controllers for each feeder; (2) a demand signal generated by a primary control loop designed to maintain a process variable that is affected by the total feed from the system; or (3) a

total flow control loop that maintains a uniform total flow by summing the individual feed rates. The last mentioned provides feedback to a total flow setpoint controller which, in turn, provides the demand signal to the individual feeder controllers.

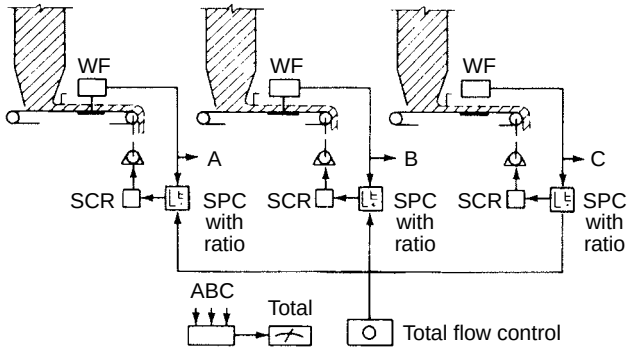

Fig. 1. Multiunit proportioning system involving the simultaneous blending of three bulk materials. WF = weigh feeder; SPC = set point controller; SCR = silicon-controlled rectifier drive.

Digital blending systems provide the most accurate means for automatic, continuous-control flow of bulk materials. They are dependent entirely on the accuracy of the digital pulses transmitted from the individual weigh feeders — with a control accuracy of plus or minus one pulse.

Automatic pacing provides the solution to systems where one or more materials may lag the remainder of the system at start-up because the material characteristics may produce a resistance to flow from the storage bins.

Belt scales are applied and installed on practically any size, length, and shape of conveyor — from 1-foot (0.3-meter) wide belts, handling as low as 1 pound (0.45 kilogram) per minute at a minimum belt speed of 1 foot (0.3 meter) per minute, to a 10-foot (3-meter) wide belt handling as high as 20,000 short tons (18,000 metric tons) per hour at speeds up to 1000 feet (300 meters) per minute.

The basic design and applications of a conventional belt conveyor scale include a weigh platform (or weigh bridge), on which are mounted standard conveyor idlers used to sense the weight of the material passing over it. A belt-speed pickup system measures the speed of the conveyor belt. Weight and speed signals are transmitted to a multiplier whose product or true rate output signal is integrated and displayed on a continuous totalizer. The rate, of course, is equal to weight times speed. The basic components used to sense the weight and speed may be mechanical, electrical, pneumatic, or hydraulic.

Of a different design principle is the loss-in-weight feeder. The decreasing weight of the material in the weigh hopper is continuously sensed and compared with a diminishing programmed setpoint which is preestablished to satisfy the flow rate desired to process. The deviation between these two signals is measured and converted for corrective action to the feeder whose speed is adjusted accordingly to maintain the programmed set point — hence the desired rate of flow. When the material in the weigh hopper reaches a selected low-level point, the hopper is quickly refilled to a selected higher level, thereby permitting uninterrupted flow rate to process.

FEEDER (Parts). A mechanical device used to orient parts of a wide variety of shapes, sizes, and materials (metal, wood, glass, plastic, rubber, and ceramic) for feeding to processing, manufacturing, assembly, and packaging operations. The parts may range from 0.02 inch to 12 inches (0.5 millimeter to 30.5 centimeters) in length. The device can be driven electromagnetically or pneumatically. Devices of this type are very important in automation systems.

FEEDER (Vibratory). A mechanical device used to provide controlled bulk material flow from storage to processes, or to and from various processes. Generally, these feeders can be driven hydraulically, electromechanically, pneumatically, or electromagnetically.

The electromagnetic vibratory feeder is basically a two-mass spring-connected system. One of the masses is the trough in which the bulk material flows; the other mass is the base or reaction mass. The two masses are connected through a set of leaf springs, which allow the two masses to vibrate relative to each other. The electromagnetic feeder creates vibratory feeding at a steady 3,600 vibrations per minute from a half-wave rectified 60-cycle alternating current. The feeders have no rotating parts, bearings, eccentrics, or sliding joints, which eliminate the need for lubrication and minimize wear.

In order for the two-mass driven system to take advantage of the natural magnification factor, the system must have its natural vibration frequency close to the operating frequency. This is referred to as subresonant tuning, that is, operating below the resonant frequency. A subresonant feeder can operate favorably regardless of high headloads on the feeder that may be caused by large hopper openings, wide heavy troughs, or the need to convey material a considerable distance from the hopper to the end of the trough. In addition to headload, the damping effect of the bulk material being handled must be considered in feeder design and selection. The damping effect of the material is a direct measure of the energy that is absorbed by the material moving from the hopper along the vibrating trough. Headloads, when considered alone, tend to cause a feeder to increase in amplitude under the effects of this load. The damping effect tends to decrease the amplitude. In practice, as proved by tests, the two effects tend to offset each other in a subresonant-tuned feeder. The general result — a feeder system that operates at reasonably constant amplitude regardless of material effects. Operating details are shown in Fig. 1.

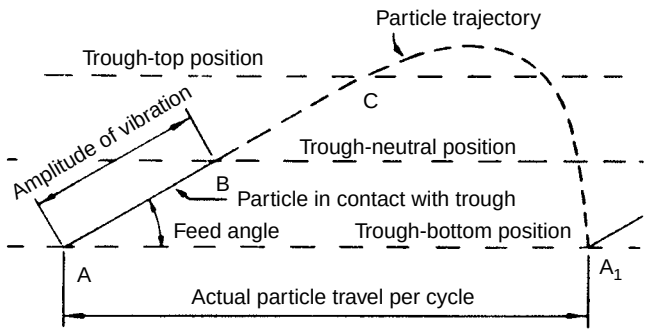

Fig. 1. Action of a vibratory feeder in moving a single particle from point A to point A_1. The trough motion approximates sinusoidal motion and the particle is in contact with the trough surface from the lowest point to approximately the mid-point of the stroke (about one-fourth of a cycle from point A to point B). At this point, the particle has been accelerated to its maximum velocity and leaves the trough surface on a free flight trajectory (trough is decelerating from point B to point C) rejoining the trough surface at point A_1, the lowest point of the stroke — which completes one cycle.

FEEDER (Volumetric). A device for metering a particulate solid by volume. Functionally, volumetric feeders for solids are analogous to volumetric flowmeters for fluids and are important elements of many process control installations. Basic characteristics of a volumetric feeding device are: (1) a determinable geometry that, in essence, becomes the basic unit of flow measurement, and (2) a controlled rate of transfer of material from the feeder to the process. These characteristics are illustrated by the rotary lock feeder shown in Fig. 1. Here, the geometry is fixed for a given size unit by cross-sectional area A. This is the area bounded by two adjacent vanes or lobes of the rotor, the housing, and the width of the rotor. The rate of transfer is determined by the rotor speed, which may be fixed or variable.

The following factors are important in specifying a feeder for a particular application: particle size, bulk density, adhesion, cohesion, abrasion, moisture, segregation, degradation, and various control factors, such that the required ease and sensitivity of control may be provided. Other factors include fire and explosion prevention, operator and maintenance skills needed, and both upstream and downstream conditions that may affect flow of material to and from the feeder.

There are several types of volumetric feeders in addition to the rotary lock feeder. These include a roll-type feeder (Fig. 2), a tray feeder (Fig. 3), and a belt feeder (Fig. 4).

FEEDFORWARD CONTROL. An automatic control action in which information concerning one or more conditions that can disturb the controlled variable is converted into corrective action to minimize deviations of the controlled variable. Feedforward control action can be combined with other types of control action to anticipate and minimize deviations of the controlled variable. Predictions used in feedforward control normally are obtained by computations with relation to a mathematical model and information obtained experimentally from measurements of the process to which application of feedforward control is contemplated.

Feedback control solves the control problem by a method of trial and error, whereas feedforward control requires a much greater understanding and quantitative knowledge of the process in order that a mathematical model can be established.

There are instances in connection with very difficult automatic control situations where feedforward control will succeed where feedback control has proved inadequate. In particular, feedforward control may be well adapted to processes subject to frequent load changes and to processes involving optimal or adaptive control. Processes that require wide proportional band and long integral time often are candidates for feedforward control.

A representative feedforward control loop is illustrated in Fig. 1. In cases where errors may result from measurements, computations, and other factors in establishing the mathematical model, a remedial measure is to apply manual or automatic feedback control so as to correct for accumulated errors. A solution of this type is shown in Fig. 2. Here a level control feedback loop is used to reset the feedforward loop. A block diagram of the system is shown in Fig. 3. A non-self-regulating process is not controllable by feedforward action alone. A properly designed feedforward system will not affect the stability of feedback controllers involved.

FEEDSTOCKS. Gaseous or liquid petroleum-derived hydrocarbons or mixture of hydrocarbons from which gasoline, fuel oil, and petrochemicals are produced by thermal or catalytic cracking. It is also called charging stock. Feedstocks commonly used include ethane [CAS: 74-84-0], propane [CAS: 74-98-6], butane [CAS: 106-97-8], butene [CAS: 25167-67-3], benzene [CAS: 71-43-2], toluene [CAS: 108-88-3], xylene [CAS: 1330-20-7], maphtha, and gas oils.

See also **Petrochemicals**; and **Petroleum**.

FEEDWATER (Boiler). No boiler can operate efficiently or dependably if its heat-transfer surfaces are allowed to foul with scale or if corrosion is permitted to occur. Thus, water treatment must include conditioning of: (1) raw-water supply; (2) condensate returns from process steam or turbines; and (3) boiler water. Proper conditioning of these waters will provide freedom from deposits on internal surfaces, absence of corrosion of

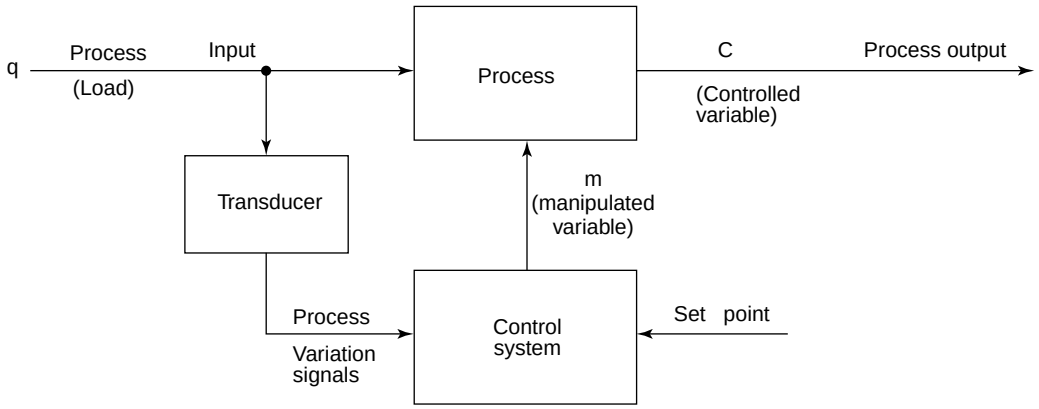

Fig. 1. Feedforward control system.

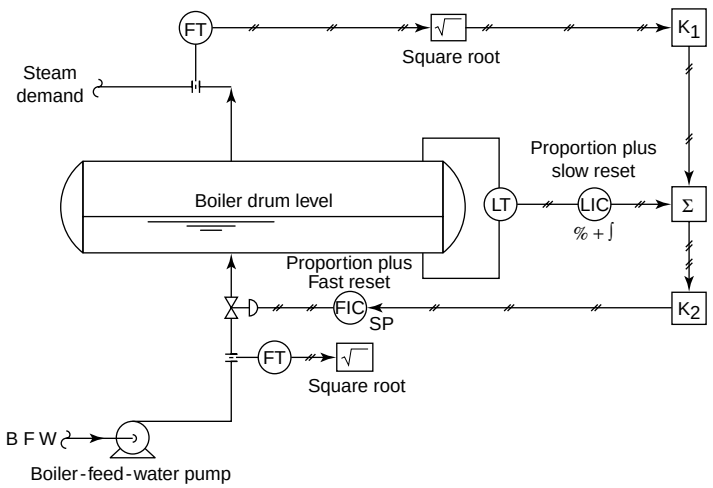

Fig. 2. Level-control feedback loop is used to reset feedforward loop in steam-generation control system.

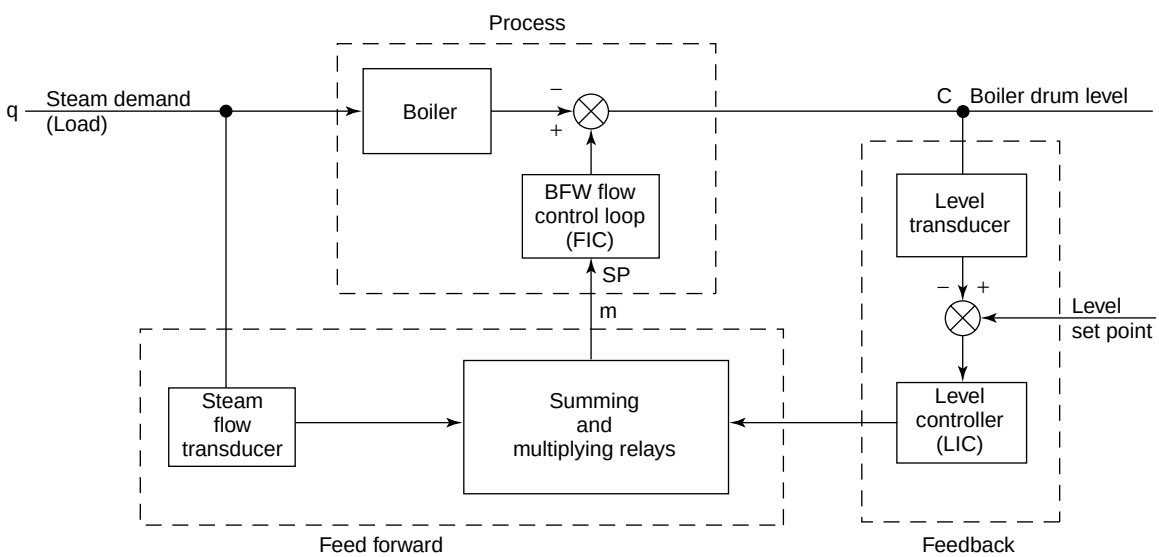

Fig. 3. Block diagram of steam-generation control system shown in Fig. 2.

internal surfaces, and prevention of foaming and carryover of boiler-water solids into the steam.

Steam lost due to process requirements, blowdown, or leakage out of the system has to be replaced; the replacement water added to the system is termed makeup water. The condensate, together with the makeup water, comprise the feedwater to the boiler. In some plants, only a small percentage of condensate is returned; in others, almost all of the steam generated is recovered as condensate. Feedwater enters the boiler and is evaporated into steam, leaving behind solids to concentrate in the boiler water. If the concentration of solids in the boiler water exceeds certain limits, the quality of steam can be impaired by carryover. Also, boiler-water solids may settle out on the boiler surfaces as sludge. The concentration of solids in the boiler water can be controlled by removing a portion of the water, either intermittently or continuously. This bleeding of a portion of the boiler water from the drum is termed blowdown.

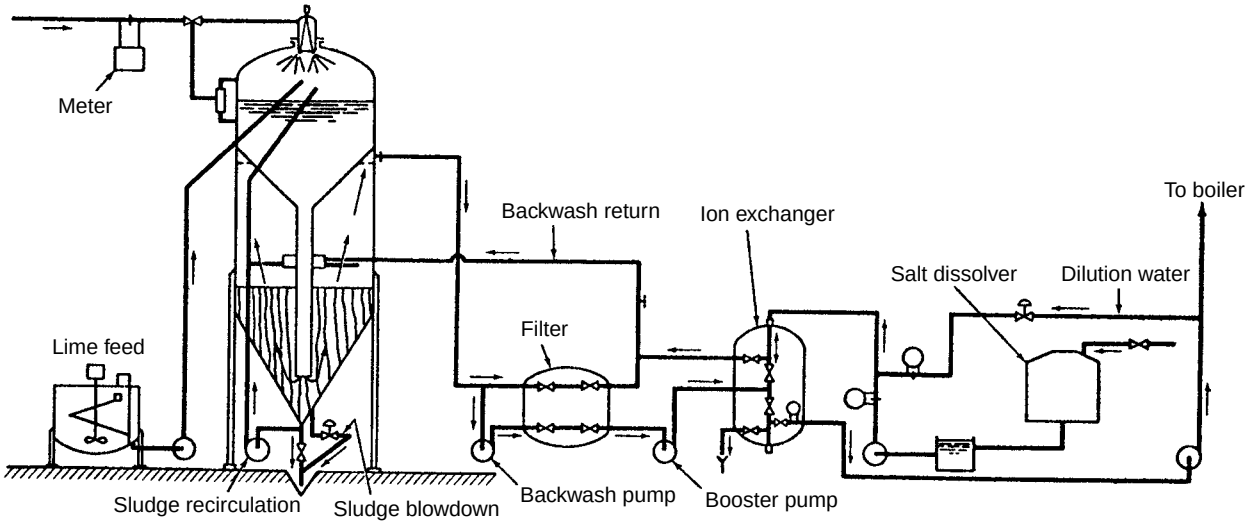

Fig. 1. Flow sheet of typical hot lime zeolite softening process.

In Universal-Pressure boilers, there are no drums to concentrate the boiler-water salts and impurities, and blowdown is not utilized. Purification takes place by continuously passing all or part of the condensate through demineralizers in a process called condensate polishing.

Raw Water Treatment. The type and amount of dissolved and suspended matter contained in raw water varies, of course, with the source, such as lake, river, or well, and notably from one geographical area to the next. The major dissolved materials in water are silica, iron, calcium, magnesium, and sodium compounds. Metallic constituents occur in various combinations with bicarbonate, carbonate, sulfate, and chloride radicals. In solution, the metal ions carry a positive charge (cations) and the bicarbonate, carbonate, sulfate, and chloride ions are negatively charged (anions). Scaling occurs when calcium or magnesium compounds in the water ("water hardness") precipitate and adhere to boiler internal surfaces. These hardness compounds become less soluble as temperature increases, causing them to separate from solution. Scaling causes damage to heat-transfer surfaces by decreasing the heat-exchange capability. The result is overheating of tubes, followed by failure and equipment damage.

Porous deposits will allow concentration of boiler-water solids. This concentration, particularly if strong alkalies are present, will result in severe corrosion of the tube surfaces. External treatment of water is required when the amount of one or more of the feedwater impurities is too high to be tolerated in the boiler system. Generally, the first step in water processing involves coagulation and filtration of suspended material.

Sodium-Cycle Softening. Also called sodium zeolite softening, this process utilizes resin materials that have the property of exchanging the hardness constituents, calcium and magnesium, for sodium. The process continues until the sodium ions become depleted or, conversely, the resin capacity to adsorb the calcium and magnesium no longer exists. When this occurs, the resin is said to be exhausted, and is regenerated by passing a solution of salt (sodium chloride) through it. Water, after passing through the zeolite process, contains as much bicarbonate, sulfate, and chloride as the raw water. Only the calcium and magnesium have been exchanged for sodium ions. There is no reduction in the overall amount of dissolved solids; neither is there a reduction of alkalinity content. When it is necessary to reduce the amount of dissolved solids, zeolite must be coupled with other methods, such as hot lime zeolite softening.

Hot Lime Zeolite Softening. In this process, hydrated lime is used to react with the bicarbonate alkalinity of the raw water. The precipitate is calcium carbonate and is filtered from the solution. To reduce silica, the natural magnesium of the raw supply can be precipitated as magnesium hydroxide, which acts as a natural absorbent for silica. These reactions are carried out in a vat or tank that is located just ahead of the zeolite softener tank. The effluent from this tank is filtered and then introduced into the zeolite softener. There is always some residual hardness leakage from the hot-process softener to be removed in the final zeolite process. The hot-lime process operates at about 104 °C. At this temperature, the potential for the exchange of sodium for hardness ions is greater than at ambient temperature. A system of this type is shown in Fig. 1.

Demineralization and Evaporation. At boiler drum pressures over 1,000 psi (68 atmospheres), demineralization or evaporation of the makeup water is generally desirable. Water that closely approaches theoretical chemical purity can be obtained by either of these processes.

Evaporation as a source of purified water does not involve ion exchange. It is actually a distillation process, consisting of evaporation, leaving most of the solids behind, and recondensation of the purified water. While evaporated water is quite satisfactory, economics generally favors demineralization.

Demineralization, like the zeolite process, involves ion exchange. The metal ions are replaced with hydrogen ions. In addition, the salt anions are replaced by hydroxide ions by means of a specially-prepared resin saturated with hydroxide ions.

Treatment of Condensate. In most cases, condensate does not require treatment prior to reuse. Makeup water is added directly to the condensate to form boiler feedwater. In some cases, however, especially where steam is used in industrial processes, the steam condensate is contaminated by corrosion products or by the in-leakage of cooling water or substances used in the process. Hence steps must be taken to reduce corrosion or to remove the undesirable substances before recycling the condensate to the boiler feedwater.

The presence of acidic gases in steam makes the condensate acidic with consequent corrosion of metal surfaces. In such cases, the corrosion rate can be reduced by feeding to the boiler water various chemicals that produce alkaline gases in the steam. The addition of neutralizing and filming amines to boiler water or condensate is one approach. Neutralizing amines (ammonia, morpholine, cyclohexylamine, and hydrazine) and filming amines (octadecylamine acetate) are volatile alkalizers that distill with the steam and neutralize acids in the condensate. Hydrazine, which is also an excellent oxygen scavenger, is included with the volatile alkalizers. It decomposes in the boiler, forming ammonia, hydrogen, and nitrogen. The ammonia provides pH control in the condensate.

Many types of contaminants can be introduced to condensate by various industrial processes. They include liquids, such as oil and hydrocarbons, as well as many kinds of dissolved and suspended materials. Each installation must be studied for potential sources of contamination. A condensate purification system used in a papermill boiler cycle is shown in Fig. 2. The resin beds not only remove dissolved impurities by ion exchange, but also serve as filters to remove suspended solids. It is necessary to backwash and regenerate these resin beds periodically.

Condensate-Polishing Systems. A condensate-polishing system is a requisite to maintain the purity required for satisfactory operation of once-through boilers. High-pressure drum-type boilers (over 2,000 psi; 136 atmospheres) can and do operate satisfactorily without condensate polishing. However, many operators recognize the benefits of condensate

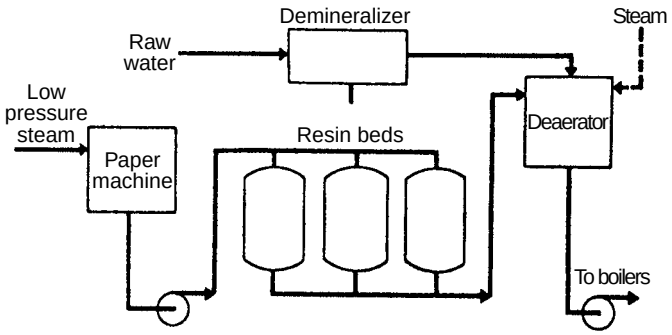

Fig. 2. Condensate purification system used in paper mill.

TABLE 1. RECOMMENDED LIMITS OF SOLIDS IN BOILER FEEDWATER

Drum Pressure	Below 600 psi	600 to 1,000 psi	1,000 to 2,000 psi	Over 2,000 psi
Total solids, ppm			0.15	0.05
Total hardness (as ppm $CaCO_3$)	0	0	0	0
Iron, ppm	0.1	0.05	0.01	0.01
Copper, ppm	0.05	0.03	0.005	0.002
Oxygen, ppm	0.007	0.007	0.007	0.007
PH	8.0–9.5	8.0–9.5	8.5–9.5	8.5–9.5
Organic	0	0	0	0

polishing in high-pressure plants, including: (1) Improved turbine capability and efficiency; (2) shorter unit startup time; (3) protection from the effects of condenser leakage; and (4) longer intervals between acid cleanings. See Fig. 3.

Feedwater Equipment. The quality of feedwater recommended for various conditions is given in Table 1. The pre-boiler equipment, consisting of feedwater heaters, feed pumps, and feed lines, may be constructed of a variety of materials, including copper, copper alloys, carbon steel, and phosphor bronzes. To reduce corrosion, the makeup and condensate must be at the proper pH level and free of gases, such as carbon dioxide and oxygen. The optimum pH level is that which introduced the least amount of iron and copper corrosion products into the boiler cycle. Although the pH level must be established for each installation, it generally ranges between 8.0 and 9.5.

Oxygen Control. The presence of gases, particularly oxygen, leads to corrosion of the boiler and cycle equipment. This type of attack will occur in an operating boiler as well as in an improperly stored idle boiler. The consequent effect of dissolved oxygen in feedwater is pitting of the internal surfaces. This is most prevalent in the economizer, the steam drum, and the supply tubes. The pitting may be general or selective. In either case, if allowed to proceed unchecked, the reliability of the unit and useful service life will be adversely affected.

The most logical approach is to expel gases from the system. The usual method is by use of a deaerating heater. This equipment must be kept in prime operating order over the complete load range. If the deaerator operates under vacuum at low loads, the entrance of air must be prevented. Oxygen concentrations at the deaerator outlet should be consistently less than 0.007 ppm. As a further assurance against the destructive effect of dissolved oxygen, a residual quantity of an oxygen-scavenging compound should be maintained in the system.

Some operators use sodium sulfite for chemical scavenging of oxygen. The amount of sulfite that can be safely carried decreases as pressure increases.

Hydrazine is an alternate scavenger, offering two principal advantages: (1) The decomposition and dissolved-oxygen reaction products of hydrazine are volatile. Consequently, they do not increase the dissolved-solids content of the boiler water, nor do they cause corrosion where steam is condensed. (2) Experience has shown that condensate pH will usually stabilize in the range of 8.5–9.5, if a 0.06 ppm hydrazine residual is maintained at the boiler inlet. This eliminates the need for pH treatment of the condensate-feedwater.

Direct Treatment of Boiler Water. Chemicals can be added directly for internal treatment of boiler water to prevent scale formations caused by hardness constituents and to provide pH control. Internal treatments must be used with extreme care to prevent buildup of total solids in the boiler water and carryover to the steam.

Much of the information in this article was furnished by Babcock & Wilcox Company and is gratefully acknowledged.

FEELING BOTTOM. As waves approach the coast and move into shallow water, the sea bed affects their propagation, leading to phenomena

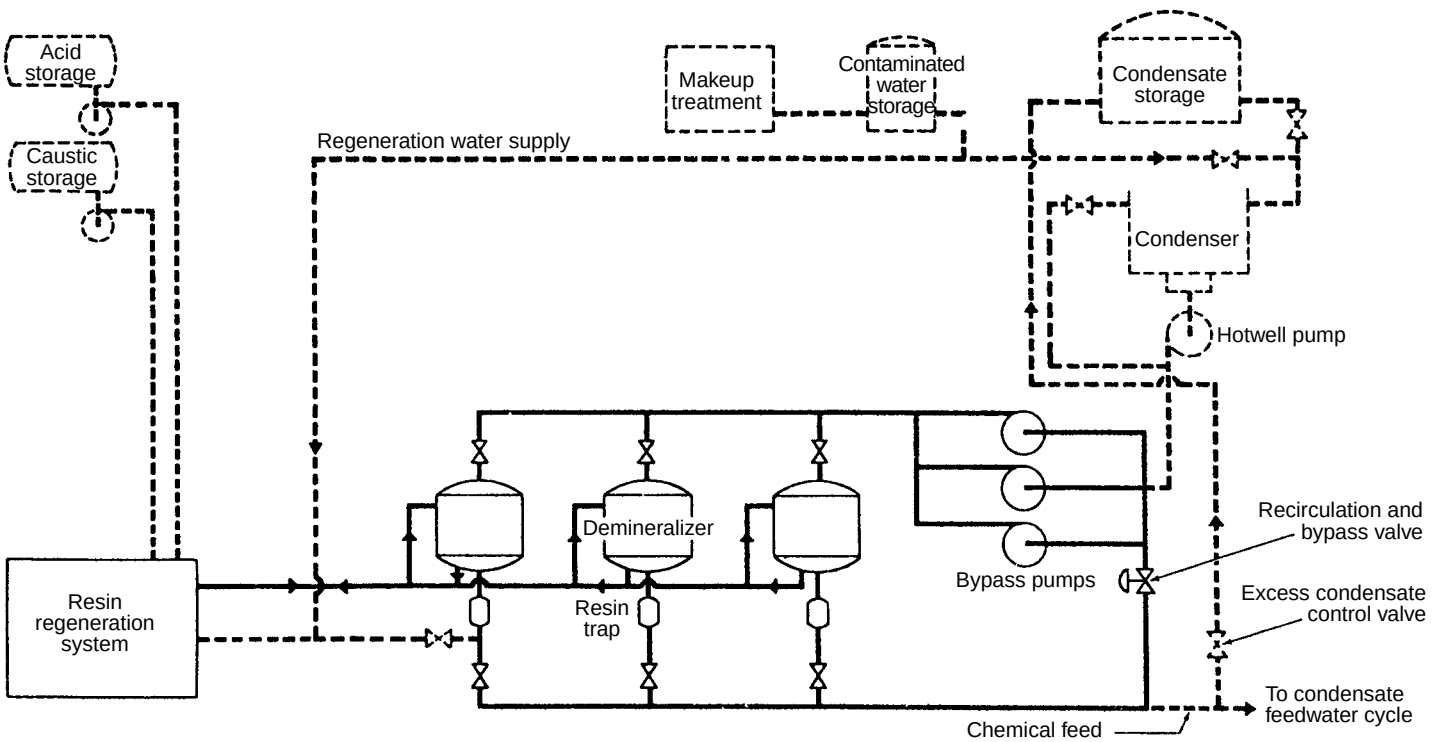

Fig. 3. Schematic diagram of condensate-polishing system with high-quality makeup treatment. (Four-bed ion exchange or equivalent.)

such as wave refraction and wave breaking. The latter is easily observed on any beach; as the waves approach the beach they steepen and break. As a rule-of-thumb, waves feel the bottom when the water depth is less than approximately one-quarter of their wavelength.

See also **Wave**; **Wave Breaking**; and **Waves and Wave Mechanics**.

FELDBERG, WILHELM SIEGMUND (1900–1993). Wilhelm Feldberg was a British neuropharmacologist who worked with Sir Henry Dale in establishing that synaptic transmission in the nervous system has a chemical basis. His later work elucidated the mechanisms by which many drugs act on the central nervous system. Born in Hamburg, Feldberg qualified in medicine in 1925 after attending a number of German universities. He immediately traveled to England, where he worked with John Langley in Cambridge and Henry Dale at the National Institute for Medical Research in London. Here he began his life's work on the role of natural chemical mechanisms in the functioning of the nervous system. After his return to Germany he continued this work until 1933 when, with the rise to power of the Nazi party, he was dismissed from his job because he was a Jew, and he returned to England to work with Dale. Apart from a brief spell in Australia before the Second World War, he remained in England for the rest of his life. See also **Central and Peripheral Nervous Systems**; and **Dale, Henry Hallett (1875–1968)**.

Feldberg brought to London a sensitive assay technique for acetylcholine, and during the early 1930s, working with Dale, he used his assay in critical experiments that showed that acetylcholine was released at the nerve terminal in response to an action potential at several sites in the peripheral nervous system (work for which Dale and Otto Loewi from Austria shared the Nobel Prize in Physiology or Medicine in 1936). After working in Melbourne, Australia and Cambridge, Feldberg returned to the National Institute for Medical Research in 1949, and began research into the pharmacology of the brain and spinal cord, devising several techniques to localize the site of action of drugs, and consequently to examine what goes wrong in disease states. See also **Acetylcholine**; and **Loewi, Otto (1873–1961)**.

He also worked extensively on the pharmacology of other substances, especially histamine, its role in anaphylaxis, its mode of action in bee and wasp stings, and the mechanism of action of nettle stings. See also **Histamine**.

FELDSPAR. Feldspar is the name of a group which includes the most important of the rock-forming minerals, making up perhaps as much as 60% of the earth's crust.

This group of minerals consists of three silicates: a potassium-aluminum silicate, a sodium-aluminum silicate, and a calcium-aluminum silicate ($KAlSi_3O_8$, $NaAlSi_3O_8$, and $CaAl_2Si_2O_8$) and their isomorphous mixtures.

The various members of the feldspar group show many characteristics in common. Crystallizing in the monoclinic and triclinic systems, they show similarity of crystal habit, cleavage and other physical properties as well as similar chemical relationships.

Orthoclase, $KAlSi_3O_8$, derives its name from the Greek words meaning right or straight, and fracture, because its two cleavages are at right angles to each other. It crystallizes in the monoclinic system and its crystals are usually prismatic; it occurs also in coarsely cleavable masses. Hardness, 6; specific gravity, 2.56–2.58; luster, vitreous to pearly; colorless to white, gray, yellow or red, rarely green. Twin crystals are not uncommon.

Orthoclase is a common constituent of many igneous rocks and is often found in huge masses in pegmatite veins. Localities for orthoclase are so numerous as to prohibit a complete list. Adularia (from Adular) is essentially a pure potassium silicate; when pearly and opalescent it is called moonstone and frequently used for jewelry. These opalescent varieties are known to be an intergrowth of orthoclase and albite. A glassy kind of orthoclase, sanidine, is found in the trachytes of the Drachenfels, Germany. Beautiful moonstones come from Sri Lanka and Switzerland; in the United States, from California and Virginia.

Orthoclase is found in the New England pegmatites, in New York, Pennsylvania, Virginia, North Carolina, Arkansas, Texas, Colorado, California, and elsewhere. Its commercial use is in the manufacture of porcelain and as a constituent in scouring powders.

Microcline, $KAlSi_3O_8$, is chemically the same as orthoclase, but belongs to the triclinic system, the prism angle being slightly less than a right angle (89°30′), hence the name microcline from the Greek meaning small, and to slope. Microcline is like orthoclase in all physical properties and can be distinguished from it surely only by optical examination. Under the polarizing microscope microcline displays a minute multiple twinning which results in a grating-like structure that is unmistakable. It is probable that much orthoclase would, upon proper examination, prove to be microcline. Amazon stone or amazonite is a beautiful green microcline occurring in the Ilmen Mountains in the Urals, Italy, Norway, Madagascar. It also occurs in the United States, in the Pikes Peak region, Colorado, Virginia, North Carolina, and sparingly in the pegmatites of New England.

The name amazon stone is derived from the application of this term to some green mineral found by the Spaniards among the aborigines of the Amazon Valley in South America. As no microcline is known to occur in the region there must have been some confusion with another green-colored substance.

A soda microcline, anorthoclase, is known, which is probably an isomorphous mixture of $KAlSi_3O_8$ and $NaAlSi_3O_8$, the sodium-aluminum silicate being in the greater proportion. The soda feldspar albite, $NaAlSi_3O_8$ and the calcium feldspar anorthite, $CaAl_2Si_2O_8$ form an isomorphous series from pure albite at one end to pure anorthite at the other, the two molecules appearing to be completely miscible one with the other. The members of this series are spoken of as the soda-lime (or lime-soda) feldspars. As a group, they are called the plagioclase feldspars (from the Greek meaning *oblique* and *fracture*, referring to the two cleavages at an angle that differs slightly from a right angle). Nearly always present are the striations, fine parallel lines, resulting from minute multiple twinning, which, never seen on orthoclase or microcline, are therefore an important diagnostic feature.

More or less arbitrarily, four intermediate plagioclase feldspars are recognized between albite and anorthite; these are listed below together with the approximate percentage of each molecule present.

	% of $NaAlSi_3O_8$	% of $CaAl_2Si_2O_8$
Albite	100 to 90	0 to 10
Oligoclase	90 to 70	10 to 30
Andesine	70 to 50	30 to 50
Labradorite	50 to 30	50 to 70
Bytownite	30 to 10	70 to 90
Anorthite	10 to 0	90 to 100

Albite is so called from the Latin, *albus*, in reference to its usual pure white color. It is a sodium aluminum silicate corresponding to the formula $NaAlSi_3O_8$. It crystallizes in the triclinic system commonly in tabular crystals. Twinning is very common, thin twinning lamellae producing a series of fine striations on certain crystal faces. There are two good cleavages at an angle of 86°24′ to each other. Hardness, 6; specific gravity, 2.62; luster, vitreous to pearly. It may be colorless to white or gray and transparent to opaque.

Albite is a relatively common and important rock-making mineral associated with the more acid rock types and in pegmatite dikes, often with rarer minerals like tourmaline and beryl. There are many famous localities in Europe in the Swiss and Austrian Alps, the Urals, the Harz Mountains, in Italy, France, and Norway. Brazil has yielded fine specimens. In the United States, notable localities are Paris and Auburn, Maine; Chesterfield, Mass.; Haddam, Connecticut; Amelia County, Virginia; and the Pikes Peak region

of Colorado. It is used in the ceramic industries and also in the manufacture of artificial teeth.

Anorthite was named by Rose in 1823 from the Greek meaning oblique, referring to its triclinic crystallization. The physical properties are essentially the same as for albite, except that the specific gravity of anorthite is somewhat greater, 2.74–2.76. Anorthite is characteristic of the basic igneous rocks such as gabbro and basalt. Anorthite is found in the lavas of Vesuvius and Monte Somma, Italy; in Finland; Japan; and in the United States, in Sussex County, New Jersey.

The intermediate members of the plagioclase group are all very similar and with the exception of certain labradorites, cannot be distinguished from each other ordinarily save by optical means. Oligoclase is a common mineral in such rocks as granites, syenites, diorites, their extrusive equivalents and many gneisses. It is a frequent associate of orthoclase. The word oligoclase is derived from the Greek meaning little, and fracture, in reference to the fact that its cleavage angle differs slightly from 90°. Sunstone is mainly oligoclase (sometimes albite) spangled with flakes of hematite.

Andesine is a characteristic mineral of rocks such as diorites, which contain a moderate amount of silica and related extrusives, such as andesites. Because of its occurrence in these latter, andesine derives its name from them as well as from the Andes Mountains.

Labradorite is the characteristic feldspar of the more basic rock types like diorite, gabbro, andesite or basalt and it is usually associated with some one of the pyroxenes or amphiboles. Labradorite frequently shows a beautiful play of iridescent colors due to minute inclusions of another mineral. However, the labradorescent phenomenon has not been fully determined. The classic location for this mineral is, of course, Labrador, whence its name. It is a constituent there of the rock anorthosite and is found in the anorthosites of the Provinces of Quebec and Ontario, and in the Adirondack region in New York State.

Bytownite, named from Bytown, the former name for Ottawa, Canada, is a rare mineral occasionally found in the more basic rocks.

The feldspars crystallize from the magma in both extrusive and intrusive rocks; they occur as contact minerals in veins, and they are developed in many sorts of metamorphic rocks, e.g., albite schists. They may also be found as mechanical deposits in various sedimentary rocks.

FELINES. See **Cats**.

FELSITE. Felsites are defined by American geologists as dense, fine-grained, light-colored rocks rich in silica, hence classified with the rhyolites, from which some of them have been formed by devitrification. Felsites may occur as intrusive dikes but, in general, they are found as extrusive rocks. They frequently occur interbedded with volcanic ash, tuff or breccia. According to American usage, any light-colored lava whose ground mass or matrix is so fine-grained that the individual minerals cannot be distinguished by the naked eye (macroscopically), may be roughly classified as felsite, hence the prevalence of the term felsitic texture. When felsites show phenocrysts they are called felsite porphyries. The term felsite was first applied by Gerhard in 1814 to the fine ground mass (matrix) of porphyries, and is therefore one of the oldest, commonly used, petrological terms.

FEMIC. This term is used by petrologists to designate the more common ferromagnesian minerals such as pyroxene and olivine. Rocks relatively rich in femic minerals are said to be urafic.

FERGUSONITE. A mineral multiple oxide containing niobium (columbium), tantalum, and titanium, corresponding to formula Y (Nb, Ta) O_4. Essentially an oxide, or niobate-tantalate of yttrium with varying amounts of erbium, cerium, and iron. Crystallizes in the tetragonal system. Hardness, 5.5–6.5; specific gravity, 5.6–5.8; color, variable. Named after Robert Ferguson (1799–1865), of Scotland.

FERMAT, PIERRE DE (1601–1665). Fermat was a French mathematician best known for his work in number theory, many of his proofs first being published by Euler a hundred years later. He was the stater of Fermat's Last Theorem and the discoverer of the principle of least time in optics.

See also **Diophantine Equation**; **Fermat Principle**; **Fermat's Last Theorem**; **Geometry**; and **Number Theory**.

J. M. I.

FERMAT PRINCIPLE. This is a law of optics recognized nearly 300 years ago by Fermat. It states that when light proceeds by any path from a point A to another point B, the time required in its passage is either a minimum or a maximum as compared to other, arbitrarily chosen, adjacent paths. If the light is reflected from A to B by a plane surface, or is refracted at a plane surface on its way from A to B, the time is a minimum. For a curved reflecting surface, the time is a minimum if the surface has less curvature than the "aplanatic" surface osculating with it at the same point (i.e., the surface which gives rise to no spherical aberration). This holds true also for a curved refracting surface. In these cases the law is known as the "principle of least time." But, if the reflecting or refracting surface has greater curvature than the aplanatic surface at the same point, the time for the actual path is a maximum. That is, if the light could be made to follow a path through any other point of the curved surface than the one it actually passes through, it would do so in less time. For all points on a given aplanatic surface, the time is the same, and the light, if unobstructed, actually does follow paths through all of them.

FERMAT'S LAST THEOREM. In 1637, the French mathematician Pierre Fermat asserted that the equation, $x^n + y^n = z^n$ has no positive integer solution x, y, z if the exponent x is greater than 2. Fermat noted in the margin of his workbook that it was not wide enough to accommodate the proof. Since that time, numerous mathematicians have tried to construct a proof. It is known that Fermat did write down a proof of the theorem for the exponent $n = 4$ and that Leonhard Euler came up with a proof for $n = 3$. Later, in the 1840s, Ernst Kummer established a mathematical theory that allowed him to prove the theorem for several exponents. Enlarging on Kummer's work and using high-speed computers in recent years, proofs for exponents up to 150,000 have been prepared. It also has been demonstrated that counterexamples would have to be very large, with x, y, and z each having hundreds of thousands of digits. In 1988, Yoichi Miyaoka (Tokyo Metropolitan Univ.) offered a proof. However, about six weeks after his announcement, Miyaoka retracted because an obstacle was encountered. As pointed out, the theorem need only be proved for the exponent $n = 4$ and exponents that are prime numbers, because if it is true for a given exponent, then it is also true for any multiple of that exponent.

Additional interesting detail is given in the references Cipra, B.A.: *Science*, 1373 (March 18,1988) and *Science*, 1275 (June 3,1988).

FERMAT THEOREM. See **Diophantine Equation**; and **Number Theory**.

FERMENTATION. A form of respiration that requires no oxygen. There is an incomplete breakdown of food; carbon dioxide and other products, such as alcohol, are formed. The word is commonly used to refer to the conversion of sugars (and sugars derived from starch) into ethyl alcohol by the enzymes of yeast.

The process of fermentation has been used from prehistoric times in the preparation of foods and beverages, but the causative agents of fermentation were not recognized until the middle of the nineteenth century. The end-products resulting from the natural fermentation of glucose, namely, alcohol and carbon dioxide, were identified by Gay-Lussac in 1810, but it was thought that this process resulted from contact catalysis and the decay of animal or vegetable materials. This explanation

was refuted by the work of Pasteur (1857) on the lactic acid fermentation. In the course of this investigation, Pasteur determined that fermentation was caused by living cells, that different microbial species caused different fermentations, that the nitrogenous materials present served only to support the growth of the cells, that lactic acid was produced when cells (removed from the fermentation mixture) were added to a sugar solution, and that the natural fermentation yielded both alcohol and lactic acid, but that the amount of each could be altered by changes in pH. In later studies, Pasteur showed that the conversion of glucose to alcohol, $C_6H_{12}O_6 \rightarrow 2CO_2 + 2C_2H_5OH$, was caused by yeast cells growing under anaerobic conditions, thus leading to the definition that fermentation was "life without air." A more modern definition of fermentation would be those energy-yielding reactions in which organic compounds act as both oxidizable substrates and oxidizing agents. Anaerobic reactions in which inorganic compounds are utilized as electron acceptors may be termed "anaerobic respirations," whereas reactions in which oxygen serves as a terminal electron acceptor are respirations.

Almost any organic compound may be fermented provided it is neither too oxidized nor too reduced, since it must function as both electron donor and electron acceptor. In some fermentations, a compound is degraded via a series of reactions in which intermediates in the sequence act as electron donors and acceptors. In others, one molecule of the substrate may be oxidized while another molecule is reduced, or two different organic compounds may be degraded after a coupled oxidation-reduction reaction. These fermentations provide energy required for the growth of a variety of cells. In addition, many microorganisms can carry out, in appropriate conditions, a number of fermentative reactions (e.g., oxidations, reduction, cleavages) which do not yield useful energy, or do not yield sufficient energy for growth.

In view of the great variety of different compounds that may be fermented and the enzymatic capabilities of different microorganisms, it is not surprising that numerous compounds important in industry (e.g., ethyl alcohol, butyl alcohol, acetone, 2,3-butylene glycol), in the production, preservation, and seasoning of food (e.g., lactic, citric, and glutamic acids), and in medicine (e.g., vitamins are extracted from the yeast carrying out the alcoholic fermentation) may be produced most cheaply through microbial fermentations. In addition, fermentations continue to be important in the production of foods (e.g., the lactic and propionic acid fermentations in the making of cheeses), beverages (e.g., the alcoholic fermentations in the making of wine and beer), and in the leavening of breads (by the carbon dioxide produced in the equation previously given). It should be pointed out that fermentation, while sometimes requiring the least expensive processing equipment to handle, and often fairly low-cost raw materials, is not always the most economic route. At one time, nearly all industrial alcohol (ethyl) was produced via fermentation. Currently, most ethanol is prepared by the direct hydration (vapor phase, catalytic); addition of water to ethylene; or by the indirect hydration of ethanol via the sulfation-hydrolysis process. See also **Ethyl Alcohol**. However, with conservation measures possibly affecting the availability of hydrocarbons for chemicals (ethylene is produced by thermally cracking hydrocarbon feedstocks), interest in fermentation of agricultural feedstocks may return.

In addition to alcoholic fermentation, there are hundreds of other types of fermentative processes. Some of these include:

Amolytic fermentation — the fermentation of starch, but specifically it is an incomplete fermentation of starch in which simple sugars are not produced.

Butyric Fermentation — in which butyric acid is produced. The organisms producing this type of fermentation are mainly anaerobic like *Clostridium butyricum*. Some organisms, such as *Clostridium tetani*, the organism causing tetanus, and *Clostridium botulinum*, the organism causing botulism, also produce this type of fermentation.

Lactic Fermentation — in which lactic acid is produced. This is an important fermentation for the preservation of food. *Lactobacillus bulgaricus, L. casei*, and *Streptococcus lactis* are used for the manufacture of dairy products, such as sour cream. *Lactobacillus plantarum* is used in the preservation of certain vegetables, such as the production of pickles and kraut.

Controlled Oxidative Fermentations — by which a number of industrial chemicals are produced. *Citromyces*, for example, can be used for the production of citric acid from sugar. *Aspergillus niger* will yield oxalic acid by partial oxidative fermentation, but if the mold is permitted to remain in contact with the acid, it will convert it to carbon dioxide.

Some sugars such as glucose may be completely oxidized to carbon dioxide by certain bacteria, most molds, and some yeasts. Such microorganisms produce complete oxidation by fermentation. Many bacteria and yeasts are able to produce a gassy fermentation. The gaseous end product in the fermentation of vegetable products with *Leuconostoc mesenteroides* and *Lactobacillus brevis* is carbon dioxide. The gaseous end products of the coliform group are carbon dioxide and hydrogen.

Ropy Fermentation — which causes the spoilage of foods. Ropy milk is caused by *Aerobacter aerogenes, Lactobacillus bulgaricus, L. casei*, and *Alcaligenes viscosus*. Ropy bread is caused by members of the *Bacillus mesentericus* group which are identical with or are strains of *B. subtilis* or *B. pumilus*. Rope in maple syrup is produced by *A. aerogenes*.

A characteristic cultural reaction of *Clostridium perfringens* and many other clostridia is known as a *stormy fermentation*. When the organism is inoculated into milk the lactose is fermented and the casein is coagulated.

The anaerobic respiration that takes place in the muscles of higher animals, when insufficient oxygen is available for a complete breakdown of the food, is also called fermentation. Lactic acid and carbon dioxide are the products of this type of fermentation.

Fermentation is discussed in numerous other entries in this encyclopedia. In particular, see also **Enzyme**; **Ethyl Alcohol**; **Genetics and Gene Science (Classical)**; **Grapes and Wines**; **Industrial Biotechnology**; **Molecular Biology**; **Rum**; **Rye**; **Vodka**; and **Whiskey**.

FERMI. The name used by some scientists to designate a length of 10^{-15} meter $= 10^{-13}$ centimeter, a length equal approximately to the radius of a nucleon.

FERMI, ENRICO (1901–1954). Fermi was an American physicist born in Rome. It should be noted that he won a fellowship to the University of Pisa for a paper on sound waves and after only four years at Pisa, he received a Ph.D. in physics.

Fermi is remembered for first producing nuclear fission in 1934 while bombarding uranium with neutrons. He received the Nobel Prize for physics in 1938 for his pioneering work on the production of induced radioactivity by neutron irradiation. He also built, under the football bleachers at University of Chicago, the first nuclear reactor in the United States in 1942. Although it only produced one-half watt of power in one-half minute, it was a success, which gave hope for the development of the atomic bomb. Element number 100 was named fermium in his honor.

J. M. I.

FERMI LEVEL. See **Fermi Surface**; and **Solid-State Physics**.

FERMIONS. Those elementary particles for which there is antisymmetry under intrapair production. They obey Fermi-Dirac statistics. Fermionic

hadrons are called *baryons*; other hadrons are *mesons*. See also **Baryons**; and **Mesons**. The experimentally observed fermions are the leptons and baryons, each of which has a spin angular momentum of $\sqrt{3}h/4\pi$, where h is Planck's constant, which is equivalent to stating that each fermion has a spin quantum number of magnitude $\frac{1}{2}$. See **Particles (Subatomic)**.

FERMI RESONANCE. In polyatomic molecules, two vibrational levels belonging to different vibrations (or combinations of vibrations) may happen to have nearly the same energy, and therefore be accidentally degenerate. As was recognized by Fermi in the case of CO_2 such a "resonance" leads to a perturbation of the energy levels that is very similar to the vibrational perturbations of diatomic molecules.

FERMI SELECTION RULES. A set of selection rules for beta decay which state that an allowed transition between parent and daughter states must have no change of spin quantum number and no change of parity.

FERMI SURFACE. Of a metal, semi-metal, or semiconductor that surface in momentum space which separates the energy states which are filled with free or quasi-free electrons from those which are unfilled. Such a surface exists simply because the electrons obey Fermi-Dirac statistics. It is a surface of constant energy and is sometimes called the Fermi level.

If one considers an elementary model of a metal consisting of a lattice of fixed positive ions immersed in a sea of conduction electrons that are free to move through the lattice, every direction of electron motion will be equally probable. Since the electrons fill the available quantized energy states starting with the lowest, a three-dimensional picture in momentum coordinates will show a spherical distribution of electron momenta and, hence, will yield a spherical Fermi surface. In this model, no account has been taken of the interaction between the fixed positive ions and the electrons. The only restriction on the movement or "freedom" of the electrons is the physical confines of the metal itself.

A short derivation, starting with the Schrödinger equation, shows that the total energy of an electron (and thus also its kinetic energy) is given by

$$E = \bar{h}^2k^2/2m = \rho^2/2m$$

where h is Planck's constant divided by 2π, k is the magnitude of the electron wave vector, m is the mass of the electron, and ρ is its momentum. A plot of E against k is then a parabola, as shown in Fig. 1(a). The Cartesian components of those values of k which are possible solutions to the Schrödinger equation are $k_i = 2\pi n_i/L$, where the n_i's are integers and L is a physical dimension of the metal. Since for each energy value so defined there are actually two states (one for an electron with spin up; one with spin down), it can be shown that the density of energy states available to the electrons is

$$g(E) = \frac{(2m)^{3/2}}{2\pi^2\bar{h}^3}E^{1/2}$$

where $g(E)\,dE$ is the number of states in the energy range E to $E + dE$. Then $n(E)$, the number of electrons per unit volume occupying energy states in this energy range, is

$$n(E)\,dE = g(E)f(E)\,dE$$

where $f(E) = \{\exp[(E - E_f)/bT] + 1\}^{-1}$, a function characteristic of particles which obey Fermi-Dirac statistics. In this expression, T is the absolute temperature, b is Boltzmann's constant, and E_f is a parameter depending on the number of electrons involved. This turns out to be the Fermi energy. E_f can be evaluated by integrating $n(E)\,dE$ from $E = 0$ to $E = \infty$ and recognizing that the integral is equal to N, the total number of electrons per unit volume. The result (at $T = 0$ K) is

$$E_f = \frac{\pi^2\bar{h}^2}{2m}\left(\frac{3N}{\pi}\right)^{2/3}$$

At $T = 0$ K, for $E < E_f$, $f(E) = 1$, while for $E > E_f$, $f(E) = 0$. Physically, this means that the probability of a state below the Fermi level being occupied is one; whereas for states with $E > E_f$, the occupancy probability drops abruptly to zero. For temperatures greater than absolute zero, the occupancy probability drops smoothly from 1 to 0 in a range of energy of width approximately equal to bT. This shell of partially filled states gives rise to the following definition: *The Fermi level is the energy level at which the probability of a state being filled is just equal to one half.*

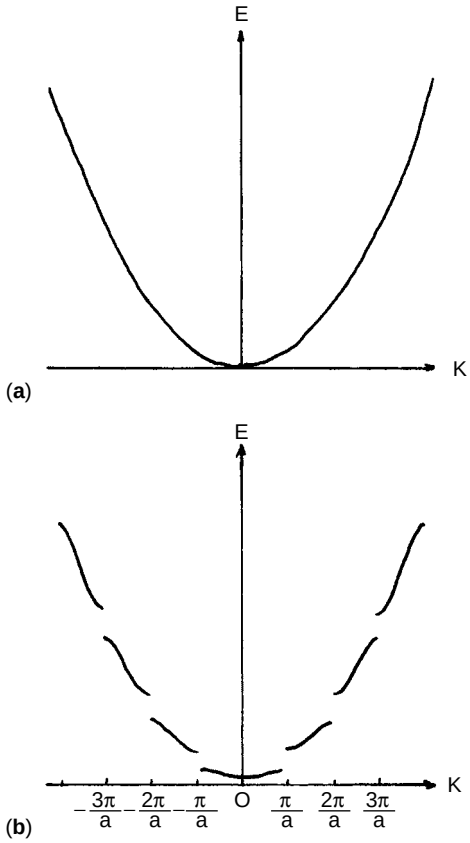

Fig. 1. (**a**) Energy plotted against wave number for the free electron model. (**b**) Energy plotted against wave number for the "quasi-free" electron model, showing energy discontinuities at Brillouin zone boundaries.

A numerical evaluation of the Fermi energy for a simple metal having one or two conduction electrons per atom yields a value of approximately 10^{-11} erg, or a few electron volts. The equivalent temperature, E_f/b, is several tens of thousands of degrees Kelvin. Thus, except in extraordinary circumstances, when dealing with metals, $bT \ll E_f$; i.e., the energy range of partially filled states is small, and the Fermi surface is well defined by the foregoing statement. It must be noted, however, that this is not necessarily true for semiconductors where the number of free electrons per unit volume may be very much smaller.

The foregoing description provides a qualitative look at the physics of metals and, under some circumstances, semi-metals and semiconductors. A more detailed analysis requires that the effects of the ions in the lattice be recognized. This can be accomplished by introducing the periodic potential due to the lattice through which the electrons must move. Then the electrons are no longer "free," but, depending on the strength and character of the potentials and the approximations used in solving the Schrödinger equation, act as "quasi-free" particles. Another approach is the "tight-binding approximation"; occasionally a combination of the two approaches is used. In any case, introduction of lattice effects changes the characteristics of the model; the total energy and kinetic energy of an electron are no longer equivalent. The periodic lattice can be described in terms of Brillouin zones, each of which is large enough (in momentum space) to accommodate two electrons per atom. The Brillouin zone boundaries appear to the electrons as Bragg reflection planes or energy discontinuities, resulting in an energy versus wave number plot as shown in Fig. 1(b).

For many metals, the "nearly free" electron description corresponds quite closely to the physical situation. The Fermi surface remains nearly spherical in shape. However, it may now be intersected by several Brillouin zone boundaries which break the surface into a number of separate sheets. It becomes useful to describe the Fermi surface in terms not only of zones or sheets filled with electrons, but also of zones or sheets of holes, that is, momentum space volumes which are empty of electrons. A conceptually simple method of constructing these successive sheets, often also referred to as "first zone," "second zone," and so on was demonstrated by Harrison. An example of such construction is shown in Fig. 2.

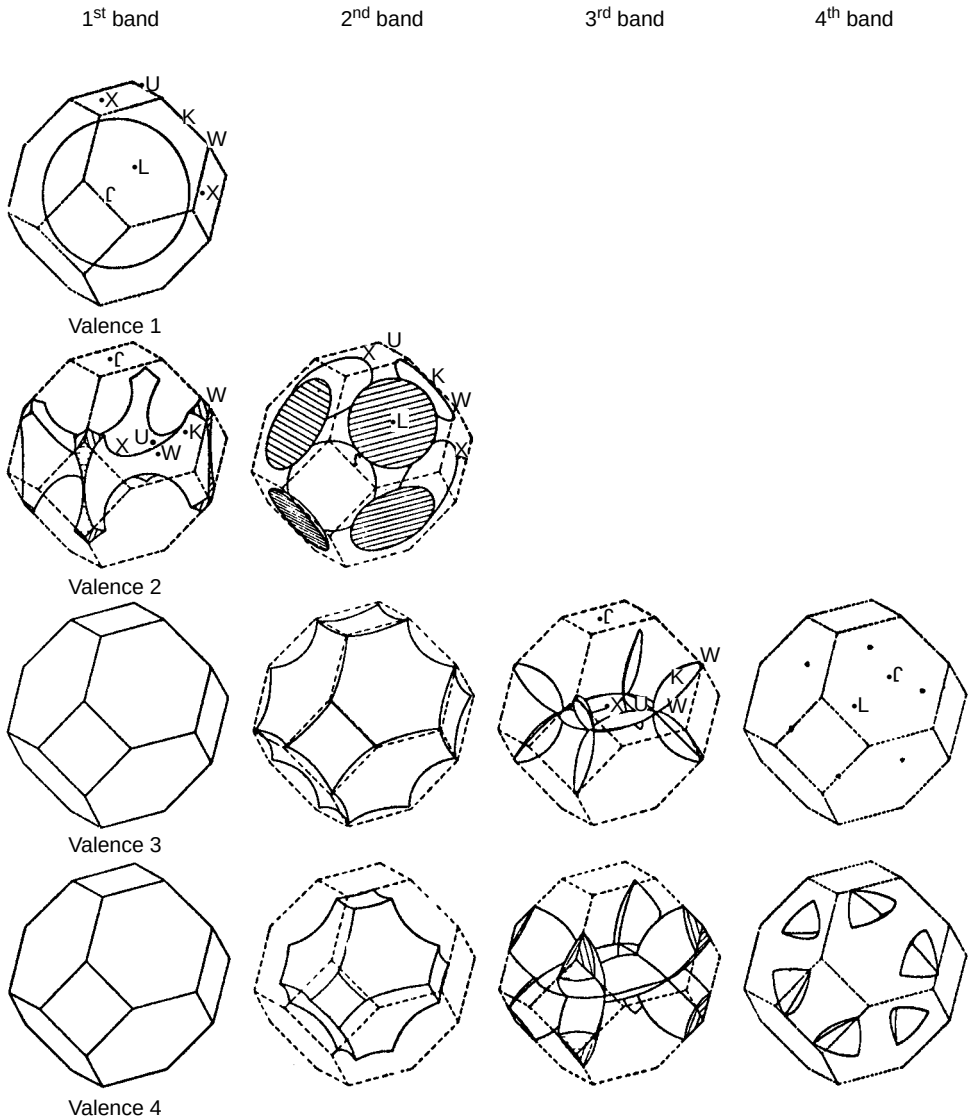

Fig. 2. Fermi surfaces in several zones or bands, for face-centered cubic metals having various numbers of "quasi-free" electrons per atom, as constructed by Harrison.

This construction works out quite well, for example, for aluminum, which has three valence electrons per atom. Experiments and more elegant theoretical calculations show that the fourth zone is totally unoccupied and that the third zone is not multiple-connected in the manner shown.

See also **Semiconductors**; and **Solid-State Physics**.

In a scholarly paper, W.E. Pickett and D.J. Singh (Naval Research Laboratory), R.E. Cohen (Carnegie Institution of Washington), and H. Krakauer (College of William and Mary) point out that, "Recent experimental results are beginning to limit seriously the theories that can be considered to explain high-temperature superconductivity. The unmistakable observation of a Fermi surface, by several groups and methods, make it the focus of realistic theories of the metallic phases. Data from angle-resolved photoemission, positron annihilation, and deHaas-van Alphen experiments are in agreement with band theory predictions, implying that the metallic phases cannot be pictured as doped insulators. The character of the low energy excitations ("quasiparticles"), which interact strongly with atomic motions, with magnetic fluctuations, and possibly with charge fluctuations, must be sorted out before the superconducting pairing mechanism can be given a microscopic basis." In their paper, the authors describe three primary experimental methods of measuring Fermi surfaces. Reference to "Fermi Surfaces, Fermi Liquids, and High-Temperature Superconductors," *Science*, **46** (January 3,1992) is suggested.

FERMIUM. [CAS: 7440-72-4] Chemical element symbol Fm, at. no. 100, at. wt. 257 (mass number of the most stable isotope), radioactive metal of the Actinide series, also one of the Transuranium elements. During the period 1953–1954, a group of scientists at the Nobel Institute of Physics (Stockholm) bombarded ^{238}U with ^{16}O ions, producing and isolating a 30-min alpha emitter. This was called ^{250}100. However, discovery of element 100 was not claimed at that time. Subsequently, the isotope was identified and the 30-min half-life confirmed. Both fermium and einsteinium were formed in a thermonuclear explosion that occurred in the South Pacific in 1952. The elements were identified by scientists from the University of California's Radiation Laboratory, the Argonne National Laboratory, and the Los Alamos Scientific Laboratory. It was observed that very heavy uranium isotopes that resulted from the action of the instantaneous neutron flux on uranium (contained in the explosive device) decayed to form Es and Fm. The probable electronic configuration of Fm $1s^2 2s^2 2p^6 3s^2 3p^6 3d^{10} 4s^2 4p^6 4d^{10} 4f^{14} 5s^2 5p^6 d^{10} 5f^{12} 6s^2 6p^6 7s^2$. Ionic radius 0.97A. See also **Chemical Elements**.

All known isotopes of fermium are radioactive. They include isotopes of mass numbers 248($t_{1/2}$ = 0.6m.), 249($t_{1/2}$ = 150s.), 250($t_{1/2}$ = 0.5 h.), 251($t_{1/2}$ = 7 h.), 252($t_{1/2}$ = 23 h.), 253($t_{1/2}$ = 4.5d), 254($t_{1/2}$ = 3.24 h.), 255($t_{1/2}$ = 22 h.), 256($t_{1/2}$ = 160 m.), and an isotope of mass number 257 which has a half-life of about 10 days. The mass number of fermium given in atomic weight tables is 253, the mass number of the isotope of longest half-life (except possibly for the last one cited). The first three decay by alpha-particle emission only; the others, through ^{255}Fm, by that and other modes, including spontaneous fission for ^{254}Fm and ^{255}Fm. Isotopes of 256 and higher decay by this mode only. Fermium isotopes are made: (1) by heavy iron bombardment of uranium and plutonium isotopes; (2) by the

action of alpha particles on californium isotopes; and (3) from several of the other transuranium elements by multiple neutron capture — or in the case of the heaviest isotopes, from einsteinium by single neutron capture.

The ion Fm^{3+} is stable, and fermium is probably exclusively trivalent.

The discovery of fermium (also einsteinium) was not the result of very carefully planned experiments, as in the cases of the other trans-uranium elements, but fermium and einsteinium were found in the debris of an atomic weapon test in the Pacific in November 1952. Researchers, using the Oak Ridge High Flux Isotope Reactor (HFIR) which produced 3.2-hour ^{254}Fm, determined the magnetic moment of the atomic ground state of the neutral fermium atom with a modified atomic beam magnetic resonance apparatus. In essence, this observation represented that of a macroscopic property of the metallic 0-valent state of fermium.

FERNS. Members of a relatively small division of the plant kingdom, the ferns (*Filicales*) comprise about 4,500 species of plants, few of which are very large. But in past times, and especially in the Carboniferous period, plants of this division were more numerous and many of them of very large size.

At the present time, the ferns are found in nearly all parts of the world, especially in regions where there is plenty of moisture. They are particularly numerous in the tropics. There also the largest of the ferns, called tree ferns (Fig. 1), are found. These tree ferns have an erect usually unbranched trunk bearing at its top a crown of much dissected leaves of large size. Tree ferns are from 10–30 feet in height; a few may reach a height of 50 feet (15 meters).

Fig. 1. Fern fronds typical of the finely divided leaves found in ferns.

In nearly all ferns the stem is a slender structure. In many species it grows underground as a creeping horizontal rhizome; in other species it is shorter and erect, but seldom rises much above the surface of the ground. From the stem numerous fine wiry roots extend into the ground. The leaves of ferns having creeping rhizomes are borne singly at the nodes; those of erect-stemmed ferns are borne in a group that forms a close crown. In many ferns the leaf, often called a frond, is pinnately compound, and the individual pinnae themselves compound. Other ferns have entire leaves.

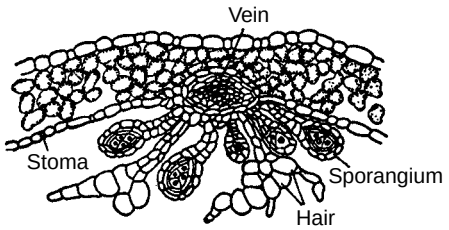

Fig. 2. Section through leaf and sorus of *Polypodium*, showing sporangia in various stages of development.

Young leaves are circinately coiled, the tip of the leaf being in the center of a tight coil, which unrolls from the base upward. Often these young leaves are covered with a mass of dense brown hairs. On the lower surface of the frond reproductive bodies are formed. In many ferns these are found on all pinnae; in others they occur only on special pinnae which are commonly very much modified in size. These reproductive bodies are commonly borne in compact groups called sori, which are often covered by a protective structure, the indusium. The reproductive bodies are stalked sporangia containing spores, which are freed by the action of certain special cells of the sporangium. (Fig. 2.) These cells have thick inner walls and in many ferns form a distinct row called the annulus. When the atmosphere is dry the cells of the annulus of a mature sporangium lose water and gradually contract. As a result, a considerable strain is exerted by the thin outer wall of these cells, so that the annulus is pulled backwards, a break occurring in a group of thin-walled cells known as the stomium. Finally the tension becomes too great and the annulus snaps back violently, catapulting the spores out of the sporangium (Fig. 3).

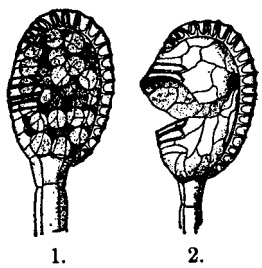

Fig. 3. Fern sporangia: (**1**) unopened sporangium filled with spores; (**2**) empty sporangium after the annulus has returned to its first position.

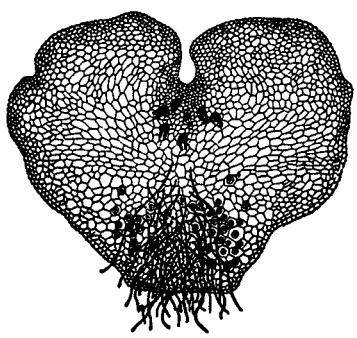

Fig. 4. Fern prothallium. View of the underside, showing archegonia near the spical notch and antheridia among the rhizoids near the base.

These spores, carried by air currents to a region where moisture is sufficient, germinate. They do not, however, form a new fern plant. Instead they develop a small delicate green plant called the prothallium (Fig. 4). In many ferns this is a heart-shaped body one cell thick. In others it is a branched object resembling certain species of algae, and in still other ferns it is a small tuberous body. From the lower surface of the prothallium numerous short rhizoids grow down and anchor it firmly in the substratum. On the lower surface also, reproductive bodies are formed. These consist of two kinds, commonly found on the same prothallium. One, usually

in the basal portion of the prothallium is the antheridium (Fig. 5a). An antheridium is a small multicellular organ in which are formed many small sperms. Fern sperms are spirally coiled cells each having a group of cilia at the tip. The female sex organ is the archegonium (Fig. 5b). These are commonly found near the notch of the prothallium. Each archegonium is a small organ consisting of a basal layer of cells surrounding the single large egg cell and a short tube surrounding a row of cells known as the neck cells. These break down, forming the neck canal, through which the sperm swim to unite with the egg. The fertilized egg or zygote immediately starts dividing and gives rise to a new fern plant. The prothallium of the fern is the gametophyte generation. It is green and very much smaller than the sporophyte, of which it is entirely independent (Fig. 6). Water is absolutely necessary for the prothallium to give rise to a new sporophyte (Fig. 7).

The ferns are of minor commercial importance. Christmas fern, Polystichum acrostichoides, has thick evergreen leaves, which are often used for decorative purposes. This fern grows wild in open woods of the north temperate region. Another fern, the maidenhair, *Adiantum pedatum*, and related species, is frequently grown as a decorative plant because of its delicate fronds. However, the fronds wilt too quickly to be of much use if cut from the plant. Species of *Osmunda*, including the Cinnamon fern, the interrupted fern, and the royal fern, are often planted in shady places for ornament. From these ferns is obtained a coarse fiber used as a potting substance on which to grow epiphytic orchids. the commonly used Boston fern, *Nephrolepsis exaltata bostoniensis*, was derived from the tropical sword fern (*N. exaltata*). Other common decorative ferns include the New York fern, the lady fern, and evergreen wood fern.

Sometimes planted as a curiosity. *Camptosorus rhizophyllus*, the walking fern (Fig. 8) gets its name because the tips of the fronds bend down to the ground and take root. New plants are formed at these points. This is a special form of vegetative reproduction. Several ferns propagate themselves by forming small bulbils on the surface of the fronds.

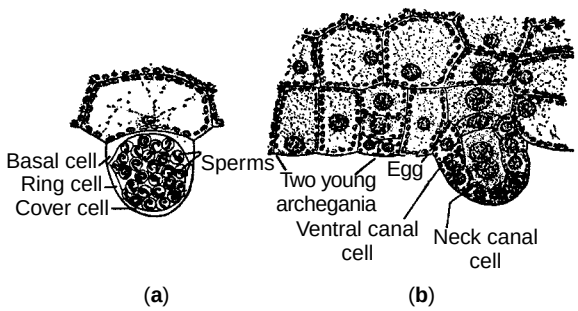

Fig. 5. (**a**) Mature antheridium of fern: (**b**) two young archegonia of fern and one mature one.

Fig. 6. Fern embryo sporophyte still attached to its parent (the gametophyte), but differentiated into its parts and making its own food. (*Left*) as seen from above; (*Right*) as seen from below.

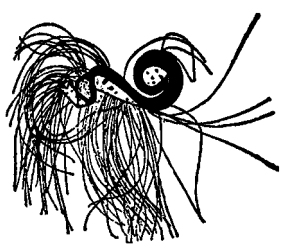

Fig. 7. A single fern microgamete, killed and stained so that parts of cell are visible.

Fig. 8. Plants of the walking fern (*Camptosorus rhizophyllus*).

Eventually these drop off and take root, giving rise to new plants. *Cystopteris bulbifera* is a fern propagating in this way. One of the most common and best-known ferns is the common brake, *Pteris* aquilina, which grows on dry hillsides and in open woods.

FERREED. A high-speed switching device with relay-like mechanical contacts used in electronic telephone switching. It consists of magnetic reeds with contacts placed in a magnetic field produced by a material having semipermanent magnetic properties. A field coil is placed around the semipermanent magnetic material to excite it. A pulse of current through the coil permanently magnetizes the material and the relay closes. A second pulse of current in the opposite direction demagnetizes the material and the relay opens.

FERREL CELL. A zonally symmetric circulation that appears to be thermally indirect (when viewed using height or pressure as the vertical coordinate) first proposed by William Ferrel in 1856 as the middle of three meridional cells in each hemisphere.

A similar type of cell was described by Matthew Maury in 1855 and James Thomson in 1857 at about the same time. The Ferrell cell has sinking motion in the same latitudes as the Hadley cell, but has rising motion in higher latitudes (approximately near 60°). The Ferrel cell is maintained by heat and momentum fluxes due to large-scale eddies and by diabatic processes; these processes are illustrated by the Kuo–Eliassen equation.

FERRET. See **Mustelines**.

FERRIMAGNETISM. A type of magnetism, macroscopically similar to ferromagnetism, but microscopically more like antiferromagnetism in that the magnetic moments of neighboring ions tend to align antiparallel. These moments are, however, of different magnitudes, and hence may still have quite a large resultant magnetization.

FERRITE. The term *ferrite* is commonly used generically to describe a class of magnetic oxide compounds which contain iron oxide as a principal component. In metallurgy, however, the term ferrite is often used as a metallographic indication of the α-iron crystalline phase.

Ferrites can be classified according to crystal structure, i.e., cubic vs hexagonal, or magnetic behavior, i.e., soft vs hard ferrites.

Some representatives of the ferrite family have long been known as magnetic minerals. For example, magnetite [CAS: 1317-61-9], Fe3O4, or loadstone was known in ancient times, ~400 BC, and magnetoplumbite [CAS: 12173-91-0], Pb(MNFe)12O19, has been known at least since the beginning of the twentieth century. The real breakthrough, however, of ferrites as important materials for electrotechnical applications took place in the early 1950s. This breakthrough built upon pioneering work in the mid-1930s followed by the theoretical framework in 1948.

The existence of ceramic magnetic materials capable of combining the resistivity of a good insulator (10^{12} ohm-cm) with high permeability was announced by Snoek (1946). Shortly thereafter, Néel (1948) introduced the term ferrimagnetism to describe the novel magnetic properties of these materials. A simple ferrite is composed of two interpenetrating ferromagnetic sublattices with magnetizations $M_a(T)$ and $M_o(T)$ which decrease with increasing temperature and vanish at the Curie point, T_c. In a ferromagnetic material, the resulting saturation magnetization M would be $M_a + M_b$. See also **Ferromagnetism**. However in a ferrite, strong antiferromagnetic interaction between sublattices results in antiparallel alignment, and $M = M_a - M_b$. In general, $M_a(T) \neq M_b(T)$, and the material behaves in most respects like a ferromagnet, exhibiting domains, a hysteresis loop, and saturation of the magnetization at relatively low applied magnetic fields. Practical values for saturation magnetization and Curie temperature range from 250–5,000 oersteds (19,984–397,887 ampere turns/meter) and from 100 to 600 °C.

Ferrites resemble ceramic materials in production processes and physical properties. The high resistance of ferrites makes eddy-current losses extremely low at high frequencies. The direct current resistivities correspond to those of semiconductors, being at least one million times those of metals. Magnetic permeabilities may be as high as 5,000 and dielectric constants in excess of 100,000. Ferrites provide design advantages over strip and powder cores for filter cores, deflection transformers, and yokes and in antenna rods, pulse transformers, delay lines, waveguide elements, and a number of other electronic components.

Ferrimagnetic materials have spinel, garnet, and hexagonal structures. A typical spinel ferrite is $NiFe_2O_4$. Other ferrites may be obtained by substituting magnetic (cobalt, nickel, manganese) or nonmagnetic (aluminum, zinc, copper) ions for some of the nickel or iron ions. That is, $Ni_{1-y}Co_yAl_xFe_{2-x}O_4$, where x and y may be varied to modify M and T_c. Yttrium iron garnet (YIG), $Y_3Fe_5O_{12}$, is the classical ferrimagnetic garnet which combines very low magnetic loss with high resistivity. Substitution of magnetic rare-earth ions (gadolinium, ytterbium, holmium, etc.) for Y and of nonmagnetic ions (gallium, aluminum) for some of the Fe ions leads to many different compositions with a wide range of M and magnetic loss. The rare-earth ions form a third magnetic sublattice with attendant magnetization M_c antiparallel to the resultant magnetization $M_{a,b}$ of the two Fe sublattices. Since M_c and $M_{a,b}$ exhibit different variations with temperature, the net magnetization may vanish twice, at F_c and at an intermediate temperature called the compensation point, T_{comp}, where $M_c = M_{a,b}$.

A typical hexagonal ferrite is $BaFe_{12}O_{19}$. Again, other magnetic ions, such as manganese, cobalt, and nickel may be introduced to produce wide variations in M and T_c. Hexagonal ferrites are characterized by large anisotropy fields with an axis of symmetry that may be either a direction of hard (planar ferrites) or easy (uniaxial ferrites) magnetization.

To distinguish among major fields of applications, ferrites can be separated into five groups: Soft, square-loop, hard, microwave, and single-crystal ferrites.

Soft ferrites have a slender S-shaped hysteresis loop with low remanence and low coercive force permitting easy magnetization and demagnetization with little magnetic loss. These ferrites are uniquely suited to low-loss inductor and transformer cores for radio, television, and carrier telephony.

Square-loop ferrites are materials exhibiting an almost rectangular hysteresis loop with two distinct states of remanence and with a coercive force of a few oersteds. All practical square-loop ferrites have a spinel structure. The Mg-Mn(Zn) system has retained an important position in computer memory applications. Lithium-nickel ferrites and more complex systems containing Li, Mn, and Al have shown stability and fast switching over a wide range of temperatures.

Hard ferrites are characterized by hexagonal structure, a hysteresis loop enclosing a large area, and a coercive force of several thousand oersteds. These ferrites can store a significant amount of magnetic energy. They have been used as permanent magnets in loudspeakers, small motors, generators, and measuring instruments.

Microwave ferrites have garnet, spinel, or hexagonal crystal structure and very low electric and magnetic loss factors. In general, the required M increases with the frequency f of applications. Substituted and pure garnets, Mg-Mn-Al ferrites and Mg-Mn ferrites are used at the lower part of the microwave spectrum where $M = 200$ to 3000 gauss is adequate. In the millimeter wave region, $f = 30$ to 100 GHz, Ni-Zn ferrites ($M =$ 5000 gauss) and hexagonal ferrites of various compositions may be used. Microwave ferrite devices, such as isolators, circulators, switches, phase shifters, limiters, parametric amplifiers, and harmonic generators are based upon interactions of rf signals with the ferrite magnetization.

Single-crystal ferrites of practical importance are rare-earth garnets grown in a flux of molten lead oxide. Some of these are optically transparent, permitting direct observation of magnetic domains. Interaction of infrared and visible light with the electron spins is called the magneto-optic effect. It permits electronic modulation of a beam of light that propagates through a single-crystal garnet. These devices are also of interest in laser technology.

Single-crystal, rare-earth garnet sheets have been grown on a substrate with a preferred direction of magnetization perpendicular to the plate. In these plates, tiny round magnetic domains called "bubbles" can be formed by an applied magnetic field. These bubbles can be propagated, erased, and manipulated to perform binary functions in computers, including logic, memory, counting, and switching. See also **Rare-Earth Elements and Metals**.

FERROELECTRIC EFFECT. The phenomenon whereby certain crystals may exhibit a spontaneous dipole moment (which is called ferroelectric by analogy with ferromagnetic — exhibiting a permanent magnetic moment). The effect in the most typical case, barium titanate, seems to be due to a polarization catastrophe, in which the local electric fields due to the polarization itself increase faster than the elastic restoring forces on the ions in the crystal, thereby leading to an asymmetrical shift in ionic positions, and hence to a permanent dipole moment. Ferroelectric crystals often show several Curie points, domain structure and hysteresis, much as do ferromagnetic crystals.

FERROELECTRIC MATERIALS. The dielectric analogs of ferromagnetic materials. Their uses parallel those of ferromagnetic materials in such applications as magnetostrictive transducers, magnetic amplifiers, and magnetic information storage devices. Rochelle salt was the first ferroelectric material to be discovered and the barium titanate ceramics are materials of this type.

FERROELECTRICS. Polarization which can be induced in nonconducting materials by means of an externally applied electric field $\overline{E}$ is one of the most important parameters in the theory of insulators, which are called dielectrics when their polarizability is under consideration. Experimental investigations have shown that these materials can be divided into linear and nonlinear dielectrics in accordance with their behavior in a realizable range of the electric field. The electric polarization $\overline{P}$ of linear dielectrics depends linearly on the electric field $\overline{E}$, whereas that of nonlinear dielectrics is a nonlinear function of the electric field. The polarization values which can be measured in linear (normal) dielectrics upon application of experimentally attainable electric fields are usually small. However, a certain group of nonlinear dielectrics exhibit polarization values which are several orders of magnitude larger than those observed

in normal dielectrics. Consequently, a number of useful physical properties related to the polarization of the materials, such as elastic, thermal, optical, electromechanical, etc, are observed in these groups of nonlinear dielectrics. See also **Dielectric Theory**.

The most important materials among nonlinear dielectrics are ferroelectrics which can exhibit a spontaneous polarization $\overline{P}_s$ in the absence of an external electric field and which can split into spontaneously polarized regions known as domains. It is evident that in the ferroelectric the domain states differ in orientation of spontaneous electric polarization, which are in equilibrium thermodynamically, and that the ferroelectric character is established when one domain state can be transformed to another by a suitably directed external electric field. It is the reorientability of the domain state polarizations that distinguishes ferroelectrics as a subgroup of materials from the 10-polar-point symmetry group of pyroelectric crystals.

Ferroelectric crystals exhibit spontaneous electric polarization and hysteresis effects in the relation between polarization and electric field. This behavior is usually observed in a limited temperature range, ie, usually below a transition temperature.

Properties

Many ferroelectrics are high band gap insulating crystals and have good transparency in both the visible and near-ir spectral regions. Qualitatively, it may be expected that the large dielectric polarizability leads to an ability to modify the refractive index ellipsoid (indicatrix) under electric fields, thus resulting in high linear and quadratic electrooptic coefficients. Much research has been devoted to seeking to develop effective broadband modulation and switching techniques for both bulk and thin-film materials by using ferroelectric electrooptic structures. Polycrystalline ceramic ferroelectrics have been processed to very high densities and good optical transparency. These materials possess new parameter combinations for modulation and imaging devices. Large photorefractive effects can also be generated in transparent ferroelectrics.

In the single-domain state, many ferroelectric crystals also exhibit high optical nonlinearity and this, coupled with the large standing optical anisotropies (birefringences) that are often available, makes the ferroelectrics interesting candidates for phase-matched optical second harmonic generation (SHG).

One area of application utilizes the interaction between the dielectric polarization and the electrical transport processes in ferroelectrics. In single dielectric crystals the effects of the domain polarizations on the drift and retrapping of photogenerated carriers give most interesting photoferroelectric effects. Of more immediate applicability, however, are the large effects of the dielectric changes at the ferroelectric phase transition on the potential barriers at grain boundaries in suitably prepared semiconducting ceramic ferroelectrics. These barium titanate–based compositions show strong positive temperature coefficients of resistivity (PTC effects) and are finding widespread use in temperature and current control for domestic, industrial, and automotive applications.

Materials

Oxygen Octahedra. An important group of ferroelectrics is that known as the perovskites. The perfect perovskite structure is a simple cubic, having the general formula ABO_3, where A is a monovalent or divalent metal such as Na, K, Rb, Ca, Sr, Ba, or Pb, and B is a tetra- or pentavalent cation such as Ti, Sn, Zr, Nb, Ta, or W. The first perovskite ferroelectric to be discovered was barium titanate [CAS: 12047-27-7], and it is the most thoroughly investigated ferroelectric material.

Simple ABO_3 compounds in addition to $BaTiO_3$ are cadmium titanate [CAS: 12014-14-1], $CdTiO_3$; lead titanate [CAS: 12060-00-3], $PbTiO_3$; potassium niobate [CAS: 12030-85-2], $KNbO_3$; sodium niobate [CAS: 12034-09-2], $NaNbO_3$; silver niobate [CAS:12309-96-5], $AgNbO_3$; potassium iodate [CAS: 7758-05-6], KIO_3; bismuth ferrate [CAS: 12010-42-3], $BiFeO_3$; sodium tantalate, [CAS: 12034-15-0] $NaTaO_3$; and lead zirconate [CAS:12060-01-4], $PbZrO_3$. The perovskite structure is also tolerant of a very wide range of multiple cation substitution on both A and B sites. Thus many more complex compounds have been found, eg, $(K_{1/2}B_{1/2})TiO_3$, $(Na_{1/2}Bi_{1/2})TiO_3$, $Pb(Sc_{1/2}Nb_{1/2})O_3$, $Pb(Fe_{1/2}Nb_{1/2})O_3$, and $Pb(Fe_{1/2}Ta_{1/2})O_3$.

The characteristic feature of the $BaTiO_3$ unit cell is the TiO_6-octahedron, which, because of its high polarizability, essentially determines the dielectric properties.

At the temperatures of the phase transitions, maxima of the dielectric constant up to 10,000 are found. Moreover, in the ferroelectric state below T_c the material becomes pyroelectric and shows high piezoelectric activity.

Perovskite-type compounds, especially $BaTiO_3$, have the ability to form extensive solid solutions. By this means a wide variety of materials having continuously changing electrical properties can be produced in the polycrystalline ceramic state.

$PbZrO_3$–$PbTiO_3$–Based Materials. Since the middle of the 1950s, solid solutions of $PbZrO_3$–$PbTiO_3$ (PZT) ceramics having the perovskite structure have gained rising interest because of the superior piezoelectric properties. At high temperatures, i.e., above T_c, the ideal cubic paraelectric structure is stable and no ferroelectric phenomena such as spontaneous polarization appear. At room temperature the materials are ferroelectric and for Ti-rich compositions ($0 \leq x \leq 0.52$) show a tetragonal distortion of the unit cell. Compositions having lower ($0.52 \leq x \leq 0.94$) Ti content have rhombohedrally distorted unit cells. Both phases are separated by a morphotropic phase boundary at $x = 0.48$. Compositions near the Zr side of the system ($0.94 \leq x \leq 1$) are antiferroelectric and have orthorhombic structure. The direction of the spontaneous polarization $\overline{P}_s$ is along one of the edges of the unit cell for tetragonal distorted compositions and along one of the space diagonals for rhombohedral distorted compositions.

A third or even a fourth and fifth phase of a complex perovskite, for example, $Pb(Mg_{1/3}Nb_{2/3})O_3$, may be added in addition to $PbTiO_3$ and $PbZrO_3$ when forming the solid solution. In the same manner, 20 different elements having similar ionic radii can be substituted in place of Mg^{2+} or Nb^{4+}, leading to a huge number of possible combinations and a multitude of compositions which have, however, generally comparable properties. At low concentrations of a complex perovskite addition, the phase relationships of the quasibinary composition are maintained. Increasing amounts of a complex perovskite reduces T_c, and pseudocubic phases begin to appear.

There is often a wide range of crystalline solid solubility between endmember compositions. Additionally the ferroelectric and antiferroelectric Curie temperatures and consequent properties appear to mutate continuously with fractional cation substitution. Thus the perovskite system has a variety of extremely useful properties.

Preparation of Ferroelectric Materials

Ceramics. The properties of ferroelectrics, basically determined by composition, are also affected by the microstructure of the densified body which depends on the fabrication method and condition. The ferroelectric ceramic process is comprised of the following steps: (*1*) selection of raw oxide materials, (*2*) preparation of a powder composition, (*3*) shaping, (*4*) densification, and (*5*) finishing.

Thin-Film Ferroelectrics. The trends in integrated circuits and packaging technologies toward miniaturization have stimulated the development of ferroelectric thin films. See also **Integrated Circuit (IC)**; and **Thin Films**. Advances in thin-film growth processes offer the opportunity to utilize the material properties of ferroelectrics such as pyroelectricity, piezoelectricity, and electrooptic activity for useful device applications. The primary impetus of the activity in ferroelectric thin-film research is the large demand for the development of nonvolatile memory devices, also called FERRAMS (ferroelectric random access memories). FERRAMS promise fast read and write cycles, low (3–5 V) switching voltages, nonvolatility, long (10^{12} cycles) endurance, and radiation hardness compatible with semiconductors such as gallium arsenide, GaAs. See also **Semiconductors: Amorphous Semiconductors**.

Several techniques have been investigated for the preparation of ferroelectric thin films. The thin-film growth processes involving low energy bombardment include magnetron sputtering, ion beam sputtering, excimer laser ablation, electron cyclotron resonance (ECR) plasma-assisted growth, and plasma-enhanced chemical vapor deposition (PECVD). Other methods are sol-gel, metal organic decomposition (MOD), thermal and *e*-beam evaporation, flash evaporation, chemical vapor deposition (CVD), metal organic chemical vapor deposition (MOCVD), and molecular beam epitaxy (MBE). See also **Sol-Gel Technology**.

The requirements of thin-film ferroelectrics are stoichiometry, phase formation, crystallization, and microstructural development for the various device applications.

Ferroelectric Ceramic-Polymer Composites. The motivation for the development of composite ferroelectric materials arose from the need for

TABLE 1. APPLICATIONS OF PIEZOELECTRIC AND ELECTROSTRICTIVE CERAMICS

Classification	Applications
High voltage generators	Gas appliances, cigarette lighters, fuses (igniters) for explosives, flash bulbs
High power ultrasonic generators	Ultrasonic cleaners, sonar, echo sounding, ultrasonic machining, atomization, pulverization
Transducers for sound and ultrasound in air	Microphones (eg, for telephones), burglar alarm systems, remote control, loudspeakers (e.g., tweeters), buzzers, medical ultrasonics equipment
Sensors	Phonograph pick-ups, accelerometers, hydrophones, detection systems in machinery, musical instruments
Resonators and filters	Radios and televisions, remote control, electronic instrumentation
Delay lines	Color televisions, computers, electronic instrumen-tation
Keyboards	Computers, printers, desk calculators, vending machines, telephones
Actuators	Micropositioners, ink-jet printers
Smart materials	Active noise control for automobiles, aircraft, and trains; active shock absorber
Electrooptic devices	Optical shutter
Composites	Hydrophones, medical imaging transducers
Miscellaneous	Voltage transformers, flow meters

TABLE 2. PROPERTIES OF RELAXOR AND NORMAL FERROELECTRICS

Property	Normal ferroelectrics	Relaxor ferroelectrics
Permittivity temperature dependence $\varepsilon = \varepsilon\ (T)$	Sharp first- or second-order transition above Curie temperature	Broad–diffuse phase transition about Curie maxima
Permittivity temperature and frequency dependence $\varepsilon = \varepsilon\ (T, \omega)$	Weak frequency dependence	Strong frequency dependence
Remanent polarization	Strong remanent polarization	Weak remanent polarization
Scattering of light	Strong anisotropy (birefringent)	Very weak anisotropy (pseudocubic)
Diffraction of x-rays	Line splitting owing to spontaneous deformation from paraelectric to ferroelectric phase	No x-ray splitting giving a pseudocubic structure

a combination of desirable properties that often cannot be obtained in single-phase materials.

The development of active ceramic-polymer composites was undertaken for underwater hydrophones having hydrostatic piezoelectric coefficients larger than those of the commonly used lead zirconate titanate (PZT) ceramics. It has been demonstrated that certain composite hydrophone materials are two to three orders of magnitude more sensitive than PZT ceramics while satisfying such other requirements as pressure dependency of sensitivity. The idea of composite ferroelectrics has been extended to other applications such as ultrasonic transducers for acoustic imaging, thermistors having both negative and positive temperature coefficients of resistance, and active sound absorbers.

To optimize a ferroelectric ceramic and polymer composite device for a certain application, it is important to define a figure of merit which includes the most sensitive parameters.

Applications

Multilayer Capacitors. Multilayer capacitors (MLC), at greater than 30 billion units per year, outnumber any other ferroelectric device in production. Multilayer capacitors consist of alternating layers of dielectric material and metal electrodes. The reason for this configuration is miniaturization of the capacitor.

The dielectric materials used in multilayer capacitors must satisfy several electrical property requirements. A high dielectric permittivity with a minimal temperature dependence is desired for a wide temperature-range application of the MLC. $BaTiO_3$-based ceramics show high dielectric permittivities; however, the dielectric permittivity of $BaTiO_3$ ceramics has a strong temperature dependence and a maximum at the Curie point.

Piezoelectric and Electrostrictive Device Applications. Devices made from ferroelectric materials utilizing their piezoelectric or electrostrictive properties range from gas igniters to ultrasonic cleaners (or welders). (see Table 1)

Composite Devices. Composites made of active-phase PZT and polymer-matrix phase are used for the hydrophone and medical imaging devices. A useful figure of merit for hydrophone materials is the product of hydrostatic strain coefficient d_h and hydrostatic voltage coefficient g_h where g_h is related to the d_h coefficient by $g_h = d_h/\varepsilon_0 K$. Electromechanical coupling properties of these materials are available.

Relaxor Ferroelectrics. The general characteristics distinguishing relaxor ferroelectrics, eg, the $PbMg_{1/3}Nb_{2/3}O_3$ family, from normal ferroelectrics such as $BaTiO_3$, are summarized in Table 2.

Relaxor ferroelectrics have been extensively investigated since the late 1970s because of the ability to generate large electrically induced strains, minimal hysteresis of the strain–electric field response, and minimal thermal strain. These materials also show promise in capacitor applications because of large dielectric permittivities. In addition to actuator and capacitor applications, a large piezoelectric effect can be induced by the application of an external electric field in relaxor ferroelectric materials possessing large polarizations. See also **Piezoelectric Effect**. The field-induced piezoelectric and elastic properties of relaxor ferroelectrics have also been investigated for transducer applications, including three-dimensional medical ultrasonic imaging devices.

Polymer Ferroelectrics. In 1969, it was found that strong piezoelectric effects could be induced in the polymer poly(vinylidene fluoride) [CAS: 24937-79-9] (known as PVD_2 or PVDF) by application of an electric field. Pyroelectricity, with pyroelectric figures of merit comparable to crystalline pyroelectric detectors of PVF_2 films polarized this way, was discovered two year later.

These discoveries were important breakthroughs for the field of electromechanical and pyroelectric devices. Fabrications of an inexpensive, completely flexible, rugged, wide area piezoelectric transducer and pyroelectric detector were realized immediately. Within a few years, a wide variety of prototype devices had been fabricated. These include audio frequency transducers, such as microphones, headphones, and loudspeaker tweeters having excellent frequency response and low distortion because of the low density lightweight transducer film; ultrasonic transducers for underwater applications, such as hydrophones, and for medical imaging applications; electromechanical transducers for computer and telephone keypads and a variety of other contactless switching applications; and pyroelectric detectors for infrared imaging and intruder detection. At least 1–2 MV/cm of poling field is required to obtain 65 mC/m^2 polarization level of PVDF thin film which is consistent with 50% crystallinity and perfect alignment.

FERROMAGNETISM. The property of certain materials that gives them relative permeabilities noticeably exceeding unity, in practice from 1.1 to 10^6. Such materials generally exhibit hysteresis, hence can be used for permanent magnets. Ferromagnetism is an extreme case of paramagnetism, and results from the spontaneous alignment of the electron magnetic moments associated with spin even in the absence of an externally applied field.

Ferromagnetism exemplifies cooperative phenomena in solids. It is characterized by a spontaneous macroscopic magnetization M (magnetic moment per unit volume) in the absence of an applied magnetic field at temperatures below a critical value, known as the Curie temperature, T_C. This property is exhibited by the transition metals, iron, cobalt, and nickel; by the rare-earth metals, such as gadolinium, terbium, dysprosium, holmium, erbium, and thulium; and by a variety of alloys, compounds, and solid solutions involving the transition, rare-earth, and actinide elements. See also **Rare-Earth Elements and Metals**. Curie temperatures range from a fraction of a degree to hundreds of Kelvin.

The apparent permeability of a magnetic material at microwave frequencies is affected (in the presence of a transverse, steady field) by the precession of electron orbits in the atoms. If the microwave frequency equals the precession frequency, resonance occurs and the apparent permeability reaches a sharp maximum. The resonance frequency depends upon the strength of the transverse field. Thus, a thin film of a ferromagnetic substance placed in a static magnetic field H is found to be capable of absorbing from an oscillating field whose magnetic vector is perpendicular to H at a frequency given by

$$\omega = \left(\frac{ge}{2mc}\right)(BH)^{1/2}$$

where b is the magnetic induction associated with H, e and m are the charge and mass of the electron, c is the velocity of light, and g is very near to 2, the Landé factor for free electrons.

The exchange interaction between electrons in neighboring atoms can be shown to depend on the relative orientations of the electronic spins. If it should turn out that parallel spins are favored, there is a strong tendency for all the spins in the lattice to become aligned, the transition to the ordered state corresponding to the Curie point. The concept of localized spins (e.g., d-electrons in the transition metals) is confirmed by neutron diffraction, but the theory is incomplete at the stage of calculating the actual magnitude and sign of the interaction.

FERROVANADIUM. See **Vanadium**.

FERTILE MATERIAL. Material that is not in itself fissionable, but that, in a nuclear reactor, may be transformed into fissionable material through a nuclear transformation; e.g.:

$$^{232}\mathrm{Th} + n \longrightarrow {}^{233}\mathrm{Th} \xrightarrow[23\ \mathrm{min}]{\beta-} {}^{233}\mathrm{Pa} \xrightarrow[27.4\ \mathrm{days}]{\beta-} {}^{233}\mathrm{U}$$

the ^{233}U is fissionable.

FERTILITY. See **Infertility**.

FERTILIZATION (Animal). See **Embryo**; **Gonads**; and **Hormones**.

FERTILIZATION (Plant). See **Flower**; and **Pollination**.

FERTILIZER. A substance, but often a combination of substances, of organic composition, natural and/or manufactured, in solid or liquid slurry forms (in some cases in the gaseous phase) made available to plants to promote normal, healthy, and often vigorous growth. Most frequently added to soils, fertilizers also are applied directly to plant parts above ground (foliar sprays), in nutrient fluids as furnished in hydroponic systems, and by irrigation systems.

Unless poisoned or severely leached, some soils still may retain some of the nutrients required by growing plants and may support plants of a weak, straggly nature, with submarginal yields and poor quality for a number of years. Some soils may be generally poor, that is, they originally did not contain any of the primary plant nutrients in adequate concentration; or they may be poor soils because they have an imbalance of nutrients. It should be stressed that the proper chemical nutrients must be present along with suitable physical properties of the soil if highest yields and quality are to be achieved. A given soil may be classified as generally rich and yet lack the needed concentration of only one or two micronutrients. Further, considering the soil-plant system, soils should be customized to the needs of specific crops; or, in reverse, certain crops should not be planted on soils that are severely out of balance with their needs.

Because of the intensity of cultivation in many regions of the world, notably among the larger producers of food and fiber crops (where there is repetitive use of the same tracts of land year after year), the uniformity of nutrient content, as may have been present in the virgin soil, cannot be assumed. In fact, experience has shown that the same soil class may vary widely in nutrient content from one field to the next. The ability of soils to provide plant nutrition is a reflection of how the soils have been artificially treated (fertilized and conditioned) over the remote and recent past and what kinds of crops have been grown on them. With increasing use of control chemicals, soils require increasing frequency of testing and analysis, not only for required plant nutrients, but also for the possible presence of chemicals that tend to accumulate rather than dissipate downward to deeper ground levels or to the groundwater. Some substances may not be biodegradable and hence they may be present from one growing season to the next.

Particularly during the last few decades, astute growers have learned to depend upon reliable scientific analysis of their soils, augmented by tissue analyses of plant parts, and sometimes total plant analysis, as a basis for planning an annual fertilizing program. Perhaps not sufficiently stressed are problems that can arise from overfertilization as well as from underfertilization. Crops vary immensely in their ability to tolerate deficiencies and excesses of nutrients. Overfertilization also can cause serious pollution problems. Overfertilization also adds a needless element to the cost of food production.

Basic Fertilizer Functions. Major reasons for adding fertilizer to soils and plants include: (1) replenishment of chemical elements that have been reduced or exhausted by the soils to the crops previously grown or leached from the soils (as the result of poor tillage practices, overirrigation, natural flooding, and, in some cases, adding nutrients that are naturally deficient in a given type of soil); and (2) customizing the nutrient content of soils to particular growing objectives.

Fertilization, in combination with irrigation, has been responsible for converting vast semiarid and arid lands with lean soils into land useful for production of a number of important food and fiber crops. This effective combination is particularly important to many of the developing countries that have large holdings of land in these categories.

Although essentially self-evident, the fact that crops exhaust the soil of key chemical ingredients is made even clearer by examination of Table 1.

TABLE 1. CONSTITUENTS OF ASH OF NORMAL CROPS

Crop and Part	Pounds of Constituent Removed per Acre of Ground (Kilograms per Hectare given in parentheses)								
	Silica	Potash	Soda	Magnesia	Lime	Ferric Oxide	Chloride	Sulfate	Phosphate
Grain	15	14	7	2	8	1	0	0	36
	(16.8)	(15.7)	(7.8)	(2.2)	(9)	(1.1)	(0)	(0)	(40.3)
Straw	233	33	1	28	12	6	4	13	11
	(261)	(37)	(1.1)	(31.4)	(13.4)	(6.7)	(4.5)	(14.6)	(12.3)
Roots	27	143	17	46	18	4	12	46	26
	(30.2)	(160)	(19)	(51.5)	(20.2)	(4.5)	(13.4)	(5.5)	(29.1)
Tops	3	89	17	72	10	3	50	39	29
	(3.4)	(99.7)	(19)	(80.6)	(11.2)	(3.4)	(56)	(43.7)	(32.8)
Hay	78	38	12	45	7	1	4	9	15
	(87.4)	(42.6)	(13.4)	(50.4)	(7.8)	(1.1)	(4.5)	(10.1)	(16.8)

In the analysis, nitrogen is lost and does not appear in the ash, but other methods for analyzing for nitrogen confirm its significant content in crops. Carbon, oxygen, and hydrogen, of course, are made available to crops by way of water and the atmosphere. See Table 1.

Principal Categories of Nutrients. The nutrients required by plants fall into three categories: (1) *primary nutrients or elements* — nitrogen, phosphorus, and potassium, because they are generally required by plants in larger amounts and are often present in more limited amounts in soil; (2) *secondary nutrients or elements* — calcium, magnesium, and sulfur, because they generally are not so limited in soils and they are required in smaller amounts; and (3) *micronutrient elements*, of which there are several and which are required in very small amounts. See Table 2.

TABLE 2. PRINCIPAL CATEGORIES OF PLANT NUTRIENTS

Primary Nutrients or Elements	Secondary Nutrients or Elements
Nitrogen (N)	Calcium (Ca)
Phosphorus (P)	Magnesium (Mg)
Potassium (K)	Sulfur (S)

Micronutrients		
	General Range in Soils	
Element	Pounds/Acre	Kilograms/Hectare
Boron (B)	20–200	22.4–224
Manganese (Mn)	100–10,000	112–11,200
Zinc (Zn)	10–600	11.2–672
Copper (Cu)	2–400	2.2–448
Iron (Fe)	10,000–200,000	11,200–224,000
Molybdenum (Mo)	1–7	1.1–7.8

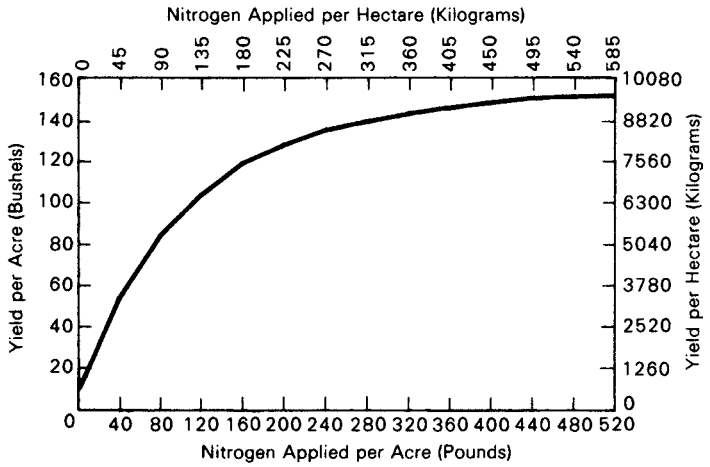

Fig. 1. Effect of nitrogen fertilizer application on crop of irrigated corn (maize) in state of Washington. It should be pointed out that the very high yields were obtained under experimental, carefully controlled conditions. Although much higher yields are obtained in some regions, the average yield in the United States is 87.3 bushels/acre (5489 kilograms/hectare). The world average is 45 bushels/acre (2829 kilograms/hectare).

Nitrogen Requirements

Although the requirements for nitrogen are well understood today, this was far from self-evident just a few centuries ago. See Fig. 1. It seems reasonably safe to postulate that the early growers of plants practiced rudimentary forms of fertilization without understanding what they were doing beyond "something taken from the soil must be returned." The latter observation in itself was rather profound for ancient peoples. It remained for the awakenings of chemistry in the 1600s and notably by the early scientists of the late 1700s and early 1800s to commence investigations of the technical links between plants and their nutrients.

Chilean saltpeter, $NaNO_3$, was the first of the chemical nitrogenous fertilizers. Ammonium sulfate, $(NH_4)_2SO_4$, made available as a byproduct of coal-gas produced in large quantities prior to wide use of natural gas, was also an early fertilizer, but followed Chilean saltpeter by several years. Ammonium sulfate is still an important source of nitrogen, but no longer holds the lead role in most parts of the world.

In the early 1900s, attempts to fix atmospheric nitrogen in a compound that could be applied directly to soil were made. During that period, nitrogen fixation was a much-discussed aspect of industrial chemistry, much as synthetic fuels are a timely topic today. For some years, calcium cyanamide, $CaCN_2$, was produced in the United States, largely as the result, at that time, of the newfound hydroelectric energy of the Tennessee Valley region. A large facility was located at Muscle Shoals, Alabama. The last plant for making $CaCN_2$ in the United States was closed in June 1971. In Norway, also because of low-cost hydroelectric energy once available, production of calcium nitrate by way of first producing nitric acid was pioneered.

The first breakthrough in the large-scale synthesis of ammonia resulted from the work of Fritz Haber (Germany, 1913), who found that ammonia could be produced by the direct combination of nitrogen and hydrogen in the presence of a catalyst at a relatively high temperature and very high pressure. See also **Ammonia**. During the interim, much-improved processes for producing synthetic ammonia have been designed.

For many years, the bulk of nitrogen fertilizers has been based upon ammonia, as synthesized. There has been an increasing trend in some major agricultural regions and countries to favor the use of liquid nitrogen for some crops. These products include anhydrous ammonia, aqua ammonia, ammonium salts in solution, and numerous combinations, such as formulations also containing phosphate salts. Because of the relatively easy solubility of these materials, some ecologists have expressed concern over so-called *nitrogen runoff*. Fortunately, however, most soils will fix ammonium ions quite rapidly, thus reducing a pollution threat.

It is interesting to observe that the compound urea, NH_2CONH_2, was discovered (in urine) as early as 1773 and first synthesized by Wöhler in 1828. See also **Urea**. Although there was an obvious connection between urea and life processes, little if any thought was given to its use as a fertilizer until after World War I, when the German firm BASF (Bosch) developed a process for synthesizing urea from carbon dioxide and ammonia. Ureaform fertilizers, now widely used, are the result of reacting urea and formaldehyde to provide a form of controlled-release nitrogen.

Urea also can be coated with sulfur (itself required by some soils) to reduce the rate of solution. And slowly soluble compounds, such as isobutylidene diurea, can be made, but because of high cost, these are marketed only to horticulturists rather than growers of commercial crops.

Although not chemical fertilizers (artificially produced), the importance of natural nitrogenous materials as returned to the soil in various degrees of *organic farming* are of extreme importance and markedly reduce the total demand for chemical nitrogen fertilizers. Significant nitrogen needs are met by returning *crop residues* to the soil. There are some negative aspects to this practice as well, however, because residues may contain insects, fungi, bacteria, and weed seeds, which generally must be controlled chemically. *Green manure* is a crop purposely grown for plowing under to enrich the soil. Animal manure also is an important contributor to the soil, not only in terms of nitrogen, but phosphate and potash as well. Also, certain crops, notably legumes, create more nitrogen for the soil than they use — this as a result of bacteria that inhabit the root zones of these plants. Collectively, these kinds of materials are sometimes called *organic fertilizer*. See Fig. 2.

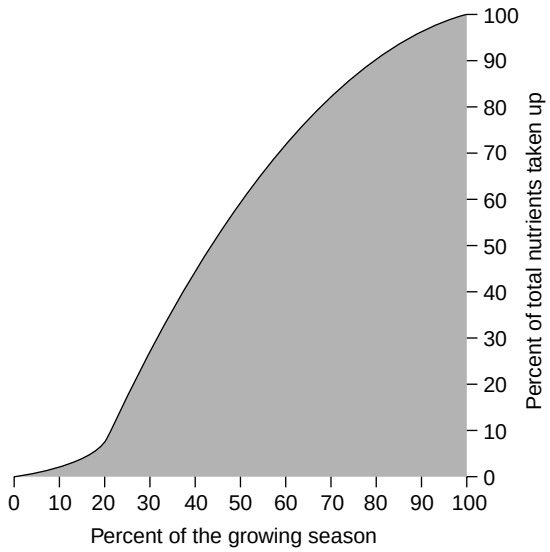

Fig. 2. Composite nutrient uptake chart representing an average of many plants. Each plant has its own specific nutrient uptake curves. (*Source: Leitch reference listed*.)

Other chemical fertilizers used as sources of nitrogen include ammonium nitrate, which contains approximately 35% nitrogen by weight. Calcium ammonium nitrate contains between 20.5 and 28% nitrogen by weight, depending upon the amount of calcium carbonate added. Ammonium sulfate nitrate contains from 26 to 28% nitrogen by weight. See also **Nitrogen** and specific nitrogen compounds described in this book.

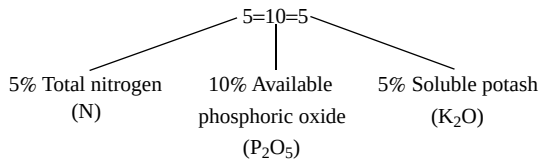
Phosphorus Requirements

Deficiencies of available phosphorus in soils are a major cause of limited crop production. Phosphorus deficiency is regarded by some authorities as the most critical mineral deficiency in grazing livestock.

Liebig and other investigators in the mid-1800s indicated that the much earlier noted fertilizing properties of bones were derived mainly from their phosphate content and that the treatment of bones with sulfuric acid increased their effectiveness in soils. With these advantages proclaimed, a large market for what was then called "chemical manure" resulted in a shortage of bones throughout the European agricultural community. Fortunately, a number of years later, several guano deposits were located in Peru and quite a bit later, phosphate minerals were located in Florida and other parts of the world. Guano fertilizers today are used mainly for special horticultural products, whereas commercial chemical phosphate fertilizers are derived from phosphate rock.

In formulating phosphate fertilizers, solubility is of particular concern. Good solubility assures availability of phosphorus to the plants. For example, in water and in alkaline and neutral soils, the apatites, which are $Ca_5(PO_4)_3R$ (where R is usually but not always fluorine), are quite insoluble and hence of little value to the soil. Tricalcium phosphate is also quite insoluble. On the other hand, these compounds are moderately soluble in acid soils and thus can be used with discretion. Somewhat in contrast, dicalcium phosphate, $CaHPO_4$, is quite soluble in acid soils and only moderately soluble in water and alkaline and neutral soils. Fortunately, monocalcium phosphate $Ca(H_2PO_4)_2$, is soluble in water and all moist soils. The presence of iron and aluminum phosphates also has an effect on total solubility, these compounds being insoluble in water, but soluble in weak acids. Some countries require total water solubility and thus monocalcium and ammonium phosphates must be used. In other areas, slight solubility in water or appreciable solubility in weak acids is adequate to meet regulations. Some humic soils can assimilate ground phosphate rock even without chemical treatment. Commonly in phosphate fertilizer manufacture, phosphorus is recovered from phosphate rock. See also **Phosphorus**; and **Phosphoric Acid**.

Nomenclature. Because the ammonium phosphate fertilizers contain two of the primary plant nutrients, it is pertinent at this point to briefly comment on the manner in which these fertilizers are named. A series of three numbers, separated by dashes, is used to indicate the primary nutrient content of fertilizer mixtures. In order, from left to right, the numbers show the percentage of nitrogen, phosphoric oxide, and potash:



Single Superphosphate is produced in large quantities and is the oldest of the water-soluble phosphates. The material contains about 20% P_2O_5 by weight. Single superphosphate is made by reacting ground phosphate rock with 70% sulfuric acid. This reaction results in a solid mass of monocalcium phosphate and gypsum. The fluorine and silicon evolved are removed by water scrubbing.

Wet-Process Orthophosphoric Acid contains 30–54% P_2O_5 by weight. When sulfuric acid is added to phosphate rocks in a proportion greater than needed to make single superphosphate, orthophosphoric acid, H_3PO_4, is produced. This acid is used as an intermediate in preparing other phosphates.

Triple Superphosphate is made by acidulating phosphate rock with phosphoric acid. The concentrated triple superphosphate produced is essentially monocalcium phosphate containing very little gypsum. The principle use of triple superphosphate is in mixed fertilizers to make P_2O_5 available in water-soluble form.

Ammonium Phosphates. Although several ammonium phosphates can be prepared, only the mono- and the di-compounds are produced for fertilizer use. In some processes, anhydrous ammonia is reacted with phosphoric acid, with the resultant slurry converted to solid form by drying. The ratio of ammonia to phosphoric acid can be varied between 1 and 2, and consequently several product grades can be made.

Nitrophosphates. Phosphate rock is readily dissolved in nitric acid to yield a mixture of calcium nitrate, phosphoric acid, and monocalcium phosphate. When calcium nitrate is converted to solid form, the material is highly hygroscopic and thus not desirable for packaging and storing. This is overcome by forming calcium nitrate tetrahydrate crystals through chilling and later removal by filtering or centrifuging. Ammoniation of the mother liquor produces a mixture of ammonium phosphate, dicalcium phosphate, and ammonium nitrate. These can be concentrated and prilled or granulated. Thus, in terms of the traditional fertilizer nomenclature, that is, $\%N = \%P_2O_5 = \%K_2O$, numerous product grades are possible according to raw-material ratios and process conditions. By adding potash to 20-20-0, a formulation of 15-15-15 can be obtained, as one of numerous examples.

Nonorthophosphates. If 54% orthophosphoric acid is dehydrated to remove the remaining free water, a pyro acid is yielded. Continued heating removes more waters and various insoluble compounds are formed. Evaporation by submerged combustion or under vacuum yields a eutectic between ortho and pyro acids with a P_2O_5 content of about 72% by weight. This superphosphoric acid can be ammoniated to yield liquid ammonium polyphosphate (APP) fertilizers, such as 10-34-0. Because of their strong

sequestering properties, these liquids keep impurities in solution, as well as the salts of micronutrient metals, which are insoluble derivatives of orthophosphoric acid.

APP fertilizers also are produced by reacting ammonia directly with wet-process phosphoric acid and dissolving the melt in ammonia solution to produce 10-34-0. By adding potash and a bit of clay, nitrogen-phosphorus-potassium suspensions, such as 13-13-13, are possible. If the melt is granulated, a solid with proportions 12-57-0 will result. Thus, by adding urea and potash, a wide variety of mixes (28-28-0, 19-19-19, and so on) are possible.

Potassium Requirements

Researchers in the early 1800s found that potassium is an essential plant nutrient although the details of its function were unknown. The potassium in wood ashes was first used in Europe, later to be replaced by sylvite, KCl, and carnalite, $KCl \cdot MgCl_2 \cdot 6\ H_2O$, found in deposits in Germany. During the interim, billions of tons of these materials have been located. A number of sites are continuously mined. Large reserves are found in the former U.S.S.R., Canada, and east and west Germany. Significant deposits also are found in Israel and Jordan (Dead Sea region), Spain, France, the United Kingdom, and the United States. Deposits are as water-soluble salts, such as sylvite, and minerals with varying content of magnesium.

The physiological role of potassium in life processes is described in entry on **Potassium and Sodium (In Biological Systems)**. Potassium is a usual, but variable constituent of most soils. However, available potassium may be depleted through loss arising from leaching by rain water, flooding, and over-irrigation, or through loss to crops continuously planted on a given tract. Thus, potassium is categorized as a primary nutrient. Potassium differs from most other essential constituents of plant cells in that it is not built into the cell as part of an organic compound, but rather it is an ion from a soluble inorganic or organic salt. Potassium ions may chelate with cellular constituents, such as polyphosphates. The ion is of the correct size to fit into the water lattice adsorbed to the proteins in the cell. In general, potassium ions are attracted to protein or other colloidal or structural units having a negative charge. Mucopolysaccharides within the cell, on the cell surfaces and of the intercellular structures, are of particular importance in holding potassium. Active centers or other configurational features of the proteins in the cell may be affected or altered by the potassium held by electrostatic or covalent binding. There are several enzyme systems activated by potassium.

In plants, the meristematic tissues in general are particularly rich in potassium, as are other metabolically active regions, such as buds, young leaves, and root tips. Potassium deficiency may produce both gross and microscopic changes in the structure of plants. Effects of deficiency include leaf damage, high or low water content of leaves, decreased photosynthesis, disturbed carbohydrate metabolism, and low protein content, among other abnormalities. The importance of potassium is also reflected by livestock that consumes plants and feedstuffs prepared from plant materials.

Potassium fertilizers are prepared from the potassium minerals previously mentioned. The ores are crushed, beneficiated, crystallized, and dried to commercial *potash* or *muriate* (KCl), in various grades and particles containing from 60 to 62% KCl. Relatively small amounts of other potassium salts are used as fertilizers. Some vegetables and tobacco are adversely affected by high chloride concentrations and some growers prefer to use potassium sulfate, K_2SO_4, or potassium nitrate, KNO_3.

Potash is frequently applied to the soil along with salts containing nitrogen and/or phosphoric oxide, P_2O_5, in amounts varied for different soil and crop requirements. One method used is that of combining crushed muriate with moist nitrogen- and P_2O_5-containing compounds, followed by granulation of the mixture. Another method is that of dry-blending materials, such as urea, diammonium phosphate, and potash, and applying the mixture to the soil. The total water solubility of potash results in full initial K_2O availability in moist soils. However, in clays, when rainfall or irrigation is limited, excessive chloride build-up can be harmful.

Calcium Requirements

The role of calcium in biosystems is described in entry on **Calcium (In Biological Systems)**. Fortunately, as the fifth most abundant element in the earth's crust, calcium is usually available to plants in abundance. Nevertheless, large amounts of calcium are added to soils by virtue of the use of lime (calcium oxide, CaO) as means to adjust the pH of soils. Among many reasons why soil pH is so important are the effects of acidic soils on the availability of manganese, a micronutrient, and also of aluminum, more recently identified as toxic to some crops. The use of dolomitic lime, $CaMg(CO_3)_2$, also is an effective way to correct magnesium deficiencies. Agricultural lime is not water soluble and, therefore, it will not correct soil acidity immediately after application.

Sulfur Requirements

The role of sulfur in biosystems is described in entry on **Sulfur (In Biological Systems)**. Sulfur in some form is required by all living organisms. Among important sulfur-containing compounds are the amino acids cysteine, cystine, and methionine; the vitamins thiamine and biotin; and certain complex lipids, such as sulfatides, among others. In the chain from soils to plants to animals, including humans, inorganic sulfur (sulfate ion, SO_4^{-2}) is taken up by plants and converted within the plant to organic compounds (sulfur amino acids). The most important feature of sulfur in the food chain is that plants use inorganic sulfur compounds to make the aforementioned amino acids, whereas animals use the sulfur amino acids for their own processes and excrete inorganic sulfur compounds.

Although sulfur is a widespread element in the earth's crust, ranking as the 14th element in abundance, it is obviously less abundant than calcium and, further, it is not so evenly distributed. Thus some soils show sulfur deficiency. The trend toward high-analysis fertilizers without sulfur can create a need for more deliberate use of sulfur fertilizers.

Sulfur is present in ammonium sulfate, used as a fertilizer, but ammonium sulfate is only one of many fertilizers that may be used. Elemental sulfur and sulfur-containing compounds are also used for controlling various plant pests. The soils also pick up sulfur from air pollution. Nevertheless, soil analysis should be made to provide an accurate diagnosis of whether or not a particular soil may require additional sulfur.

Magnesium Requirements

The role of magnesium in biosystems is described in entry on **Magnesium (In Biological Systems)**. Magnesium is generally abundant in the earth's crust, ranking 8th in abundance. Nevertheless, magnesium deficiencies are quite common. Magnesium deficiency is a fairly common cause of poor crop yields, especially among crops produced on sandy soils. Accumulation of magnesium from the soil by plants is strongly affected by the species of plant. Legumes usually contain more magnesium than grasses, tomatoes, corn (maize), regardless of the level of magnesium in the soil. A high level of available potassium in the soil interferes with the uptake of magnesium by plants, and thus magnesium deficiency can occur even if there are adequate amounts of the element in the soil. The role of magnesium highlights the systems aspects of agricultural management, exemplified by need to maintain a proper magnesium intake from pasture and from feedstuffs. When animals are fed diets primarily of grains, a proper balance among magnesium, calcium, and phosphorus must be maintained to minimize danger of urinary calculi. Magnesium deficiency among cattle (grass tetany or grass staggers) is observed most frequently when animals are first grazed on lush grass or wheat pastures, indirectly indicating the relative low uptake of magnesium by certain crops.

Magnesium deficiencies are easily corrected by applying magnesium minerals, such as kieserite or dolomite.

Micronutrients

The principal micronutrients and their deficiencies in soils of the United States are shown in Table 3. Even though the traditional micronutrients may be required only in minute quantities, deficiencies can lead to diseased crops and stunted livestock. See also entries on **Boron; Copper (In Biological Systems); Iron; Manganese; Molybdenum (In Biological Systems)**; and **Zinc (In Biological Systems)**.

Much more detail on all aspects of fertilizers, including worldwide consumption, methods of application, etc., can be found in the "Foods and Food Production Encyclopedia," (D.M. Considine, editor), Van Nostrand Reinhold, New York, 1981.

FEVER. The elevation of body temperature, above its normal range. The normal range varies slightly with the individual and with the time of day. The basic normal temperature is considered to be 98.6°F (37°C). Although a slightly lower body temperature during morning hours, as compared with later in the day, is normal, any swing of over one Fahrenheit degree during a 24-hour period is considered abnormal. Rectal temperatures usually are more reliable than those of the mouth or armpit. During diseases and disorders, body temperature may rise several degrees without permanent — damage to organs and vessels. However, a rise above approximately 108°F (42°C) indicates very rapid metabolic rates and, as the temperature increases further, it is extremely difficult but absolutely necessary to reverse these rates if the body temperature is to return to normal. A body temperature rise to about 112 to 114°F (44.5 to 45°C) usually is fatal. This is not only because of permanent damage to the neuronal cells of the brain, but also because of the virtual impossibility of reversing the individual's metabolic rates at such high temperatures.

Presentation of fever where there appears to be no obvious cause is one of the most frequently encountered confounding problems for the physician. This kind of fever is discussed later in this article.

Infection-Associated Fever. Fever occurs most commonly in infections, but may accompany a variety of other ailments. The type of fever often is characteristic for the disease, and may be described according to the constancy with which the elevated temperature is maintained. Thus, a continuous fever is one that is maintained at a fairly constant level for several days. When there are moderate fluctuations, the temperature is said to be remittent. If the temperature approaches or reaches normal during some part of the day, but rises considerably at other times, the fever is said to be intermittent. Rises in temperature may be gradual, or very sudden, following chilly sensations or shaking chills. Fever may terminate slowly by lysis or suddenly by crisis.

The mechanism of fever is best appreciated when one realizes that the normal temperature regulation of the human body is extremely reliable and amazingly precise. It is interesting to note, for example, that a healthy individual (in the nude, so that effects of clothing are eliminated) can be exposed to dry air temperatures as low as 50°F (10°C) or as high as 165°F (74°C) for many hours and still not alter the internal body temperature by over a degree or two. This regulation is possible because of the several mechanisms available to the body to control heat generation and heat loss and the unusual sensory arrangements that control these mechanisms. It is believed that fever results from an abnormal production of proteins, which find their way into body fluids during the process of certain fever-producing diseases. These proteins react upon the hypothalamus. Available mechanisms for increasing body temperature include: (1) *vasoconstriction*, which decreases the flow of blood to the skin and consequently diminishes the transfer of heat from the body surface; (2) *increased metabolism*, which releases hormones to cells, stepping up the metabolic rate, and causing increased generation of heat, and (3) *induced shivering*, termed *chill*, which always is an indication that body temperature is rising. Shivering stimulates muscular tone and hence promotes the quantity of muscle produced heat within the body. In the reverse process, during the lowering of a fever temperature, vasodilation commences, sweating starts, and there is decreased muscle tone. Sweating, by promoting evaporative cooling, is a very effective body coolant. With the wide use of antibiotics, the true course of a fever may not be observed. In a normal fever situation, the appearance of sweating after a long period of fever is termed the crisis, indicating that the body temperature is commencing to lower toward normal. Consequently, the bacteria, virus, or other cause of the fever has been overcome.

Fever of Undetermined Origin (FUO). A low-grade fever that persists (weeks to months) in a patient without obvious cause is one of the most baffling challenges facing the physician. Frequently, such situations are not brought to the attention of a physician for a period of time during which the patient is not unduly concerned. In 1961, Petersdorf and Beeson made a marked contribution toward studying such cases by placing FUO into three categories, as follows. (1) The duration of fever is over 3 weeks; this criterion eliminates the usual febrile (fever-producing) illnesses and the fever (pyrexia) sometimes present in the postoperative patient. (2) The fever may periodically exceed 101°F (38.3°C); this criterion rules out persons, frequently young women, who "naturally" have mild hypothermia of 99.1–110.4°F (37.3–38°C). (3) The nature of the condition is truly obscure, that is, still unresolved after a diagnostic effort extending over several days. Statistics show that, in the long run, most cases of FUO are atypical manifestations of common diseases rather than rare kinds of disorders and diseases. Research has shown a host of such atypical situations, adding to the difficulty of the problem. Fever generally has daily patterns and specific diseases may present specific alterations of these patterns, thus some clues. A part of the problem thus arises from the prior administration of antipyretics, such as salicylates, which can convert a FUO to a remittent pattern with altered daily peaks. A small number of patients with FUO are not diagnosed satisfactorily, but in such cases, the fever usually abates over a period of several months. It may be hypothesized that, in such cases, certain temperature-regulating mechanisms of the body remain unknown or are very poorly understood and that these mechanisms may malfunction for periods of time without serious consequences.

Relatively common diseases which are prone to cause FUO as an atypical symptom in a minority of patients include: (1) systemic infections, such as military tuberculosis, infective endocarditis, bacteremia resulting from chronic meningococcemia, brucellosis, and listerosis; (2) localized infections and abscesses, such as hepatic infections (liver; e.g., cholangitis), intraperitoneal infections, intra-abdominal abscesses, and urinary tract infections; (3) uncommonly seen diseases, such as psittacosis, toxoplasmosis, Q fever, and mycotic infections; (4) neoplasms, frequently associated with Hodgkin's disease, myeloma, and chronic lymphocytic leukemia; (5) granulomatous diseases, such as sarcoidosis; (6) inflammatory bowel disease; (7) alcoholic hepatitis and cirrhosis; (8) pulmonary emboli; (9) drug-induced fever; and (10) quite uncommonly, "false" elevation in temperature, usually as the result of a psychiatric disorder. This condition is sometimes called *factitious fever*.

In those cases where analysis of patient history and the data from common clinical tests do not yield a determination of cause, the physician may suggest that the patient enter a hospital. There, more-detailed tests and continuous observations can be made. Such laboratory studies may include: (1) blood-cultures (both aerobic and anaerobic); (2) serologic tests; (3) sedimentation rate determinations; (4) liver function tests; (5) skin tests; and (6) spinal fluid examination, among others. Further, the testing may include radiological studies (chest films, intravenous pyelograms, upper- and lower-gastrointestinal X-rays, bone X-rays, lymphangiograms, cholangiograms, aortograms, and celiac angiograms, among others). Radioactive and CT scans and ultrasound studies also may be made. Percutaneous liver, bone marrow, lymph node, skin and muscle, and temporal artery biopsies may be made. In extremely difficult situations, some authorities have suggested exploratory laparotomy. As pointed out by Swartz, in a few patients with FUO, in whom no helpful clues have been found during hospitalization and in whom the disease process is not very prolonged, progressive, or associated with marked weight loss, the best course may be to pause temporarily. Readmission to hospital and reevaluation of the patient some weeks later may yield a diagnosis. Up to 10% of patients with FUO seem to recover in the absence of a diagnosis of the specific fever source. Fevers that abate after several months do not necessarily recur and do not always indicate a serious underlying process, such as neoplasm or collagen vascular disease.

The medical literature is comparatively sparse in the coverage of persistent or recurring fever from causes that are not readily apparent. T.F. Duffy (reference listed) reports of a 71-year-old man who was admitted to hospital with a six-month history of sweats, unexplained fever, weight loss, and anemia. The analytical procedure followed is very interesting and, although a final determination of fever cause had not been made at the time of the report, it appeared to be related to myeloma. As pointed out in the report, "Myeloma is not recognized as a common cause of fever of unknown origin. One is therefore hesitant to come too readily to the conclusion that myeloma was the sole cause of (the patient's) prolonged fever. Indeed, the usual absence of fever with myeloma is surprising, because myeloma cells produce many cytokines that could in principle cause fever."

In late 1990, L.N. Slater and a group of researchers (University of Oklahoma Health Sciences Center) identified a motile, curved, gram-negative bacillus as the cause of persistent fever and bacteremia in patients with symptomatic human immunodeficiency virus infection. In the conclusion of a study, the investigators observed, "This pathogen may have been unidentified until now because of its slow growth, broad susceptibility to antimicrobial agents, and possible requirement of blood-cell lysis for recovery in culture. It should be sought as a cause of unexplained fever, especially in persons with defective cell-mediated immunity."

In late 1992, A.T. Berg (Yale School of Medicine) and a team of researchers reported on an apparent relationship between a fever of short duration and the occurrence of febrile seizures in children. Febrile seizures are the most common type of seizure and occur in 2 to 4 percent of all children. Approximately one-third of children who have a febrile seizure have a recurrence. The fever connection was discovered during a study to identify predictors of recurrent seizures.

Although conducted some 30 years ago, the Peterdorf-Beeson (reference listed) report remains an excellent source of information on fever of unexplained origin.

FIBER (Dietary). See **Diet**.

FIBER GLASS. Glass in fibrous form. The material generally has properties similar to the glass from which it is made except that the tensile strength may be increased up to over 100 times that of the base glass. History records the use of strands of glass for decorating vases by the early Egyptians. The famed Venetian craftsmen had a limited knowledge of drawing glass fibers, but it was not until the 1930s and 1940s that glass producers perfected a way to make fibers commercially.

Two forms of glass fibers are produced; a staple or short-length fiber or monofilament, and continuous strand composed of many-monofilaments bonded together in a threadlike form. The continuous strands are often chopped into short lengths, ranging from 1/8-inch to 2 inches (3 millimeters to 5 centimeters) or longer, and this product is referred to as chopped strand. Staple fibers are used for thermal and acoustical insulation. Continuous strands are used for yarn (as in fabrics), tire cord, and plastic reinforcement. Both thermoset and thermoplastic resins are reinforced by chopped strand. Some varieties of chopped strand are also converted to monofilament paper, which is utilized in roofing shingles, flooring materials, and other products. Products using continuous filaments have excellent tensile strength (as high as 400,000 pounds per square inch; 2759 megapascals) compared with organic fiber strengths of less than 150,000 psi (1034 megapascals).

The base glass is made by heating raw materials, such as silica sand, limestone, dolomite, clay, boric acid, soda ash, and other minor ingredients, in a high-temperature furnace. See also Glass. Typical glass-fiber compositions are given in Table 1. Fiber made from electrical-grade glass E is used most commonly for yarn, tire cord, and plastic reinforcement because of its high strength and electrical properties. Specialty glasses, although low in volume of production, fill important needs. S glass is a superior-strength glass primarily for defense applications, such as missile cases. C glass is more chemically resistant than E and is used for battery separator plates and chemical filters. Alkali glass A is used to some extent in the production of plastic reinforcement products.

TABLE 1. FORMULATIONS FOR TYPICAL FIBER GLASS TYPES

	Type of Glass. wt%				
Ingredient	E	Insulating	A	S	C
SiO_2	54	63	73	64	65
Al_2O_3	14	5	1	24	4
MgO	4	2	2	10	3
CaO	19	6	10	—	14
R_2O	0.5	16	14	—	8
B_2O_3	8	7	—	0–2	6
Fe_2O_3	0.3				
F_2	0.2	1			

Note: R = rare-earth element.

Continuous-Fiber Products. In the "direct-melt" process, shown in Fig. 1, raw materials are fed to a tank furnace to convert the mixture to glass. The glass flows to forehearths, which have platinum-alloy bushings or spinnerettes in the bottom. The bushings contain many holes, or orifices, each of which supplies a small stream of molten glass from which monofilaments are drawn. Mechanical attenuation, which produces a forming package, is accomplished by attaching the fibers to a rotating drum which turns up to 20,000 peripheral feet (6,000 meters) per minute.

The "marble-melt" process consists of producing 1-inch (2.5-centimeter) marbles by a separate tank furnace. The marbles are then fed to a bushing unit, which is heated by electrical resistance. From this point, the process is identical to the direct-melt process.

Sizing. Because of the basic character of glass, the filaments are somewhat fragile and tend to abrade each other in close contact. A protective coating or sizing is necessary for the production, processing, and end use of all continuous-fiber glass products. Generally, a fiberglass sizing or binder for textile or reinforcement products may contain: (1) a film former, generally resinous in nature, that forms a strand or thread from grouped monofilaments; (2) a lubricant, to aid in processing and end use of the fiber-glass product; and (3) additives to accomplish specified purposes, e.g., providing antistatic characteristics.

Sizings for plastic reinforcement also will have a coupling agent, such as a chrome complex, a silane, or combination of these two, to assure an interfacial bond between the glass surface and the resin matrix. Yarns for weaving normally have an oil-starch sizing. These coatings are applied before winding of the forming package.

Filaments ranging in number from 20 to 2000 are then gathered together as a thread or strand before winding. As shown by Table 2, the filaments are available in many diameters and are letter-designated. In continuous-fiber products, filaments range from designation B to U.

Continuous-filament products are designated by a letter-number system, which specifies properties important to end users. For example, listing a strand as ECK67.5 (200) 630 indicates that the material is made from E glass and is a C continuous fiber of K diameter; the strand contains 200 monofilaments and has a yield of 67.5×100, or 6,750 yards per pound. (In the metric system, yield is expressed in Tex, or grams per kilometer. The number 486,235 divided by yards per pound is equal to Tex. Hence the yield in this case would be 72 Tex). This product is coated at the bushing with 630 binder, an oil-starch type making it suitable for weaving into fabric.

Forming packages composed of wound strands normally are not supplied to industrial users without further processing. Strands are twisted and plied before being woven into fabric. A plied yarn, for example, is coated with a latex binder before being used as a tire-cord reinforcement.

End products made from continuous strand include fire-resistant curtains, reinforced tires and transmission belts, and many reinforced plastic items, such as boats, auto bodies, corrosion-proof pipe, roofing panels, and missile cases.

Staple-Fiber Products. Monofilament, short-length fibers are used for thermal and acoustical insulation, filtration, and cushioning. These products are made in basically three ways. In the high-temperature blast-jet process, 30-mil-diameter fibers or rods first are produced by a bushingtype process.

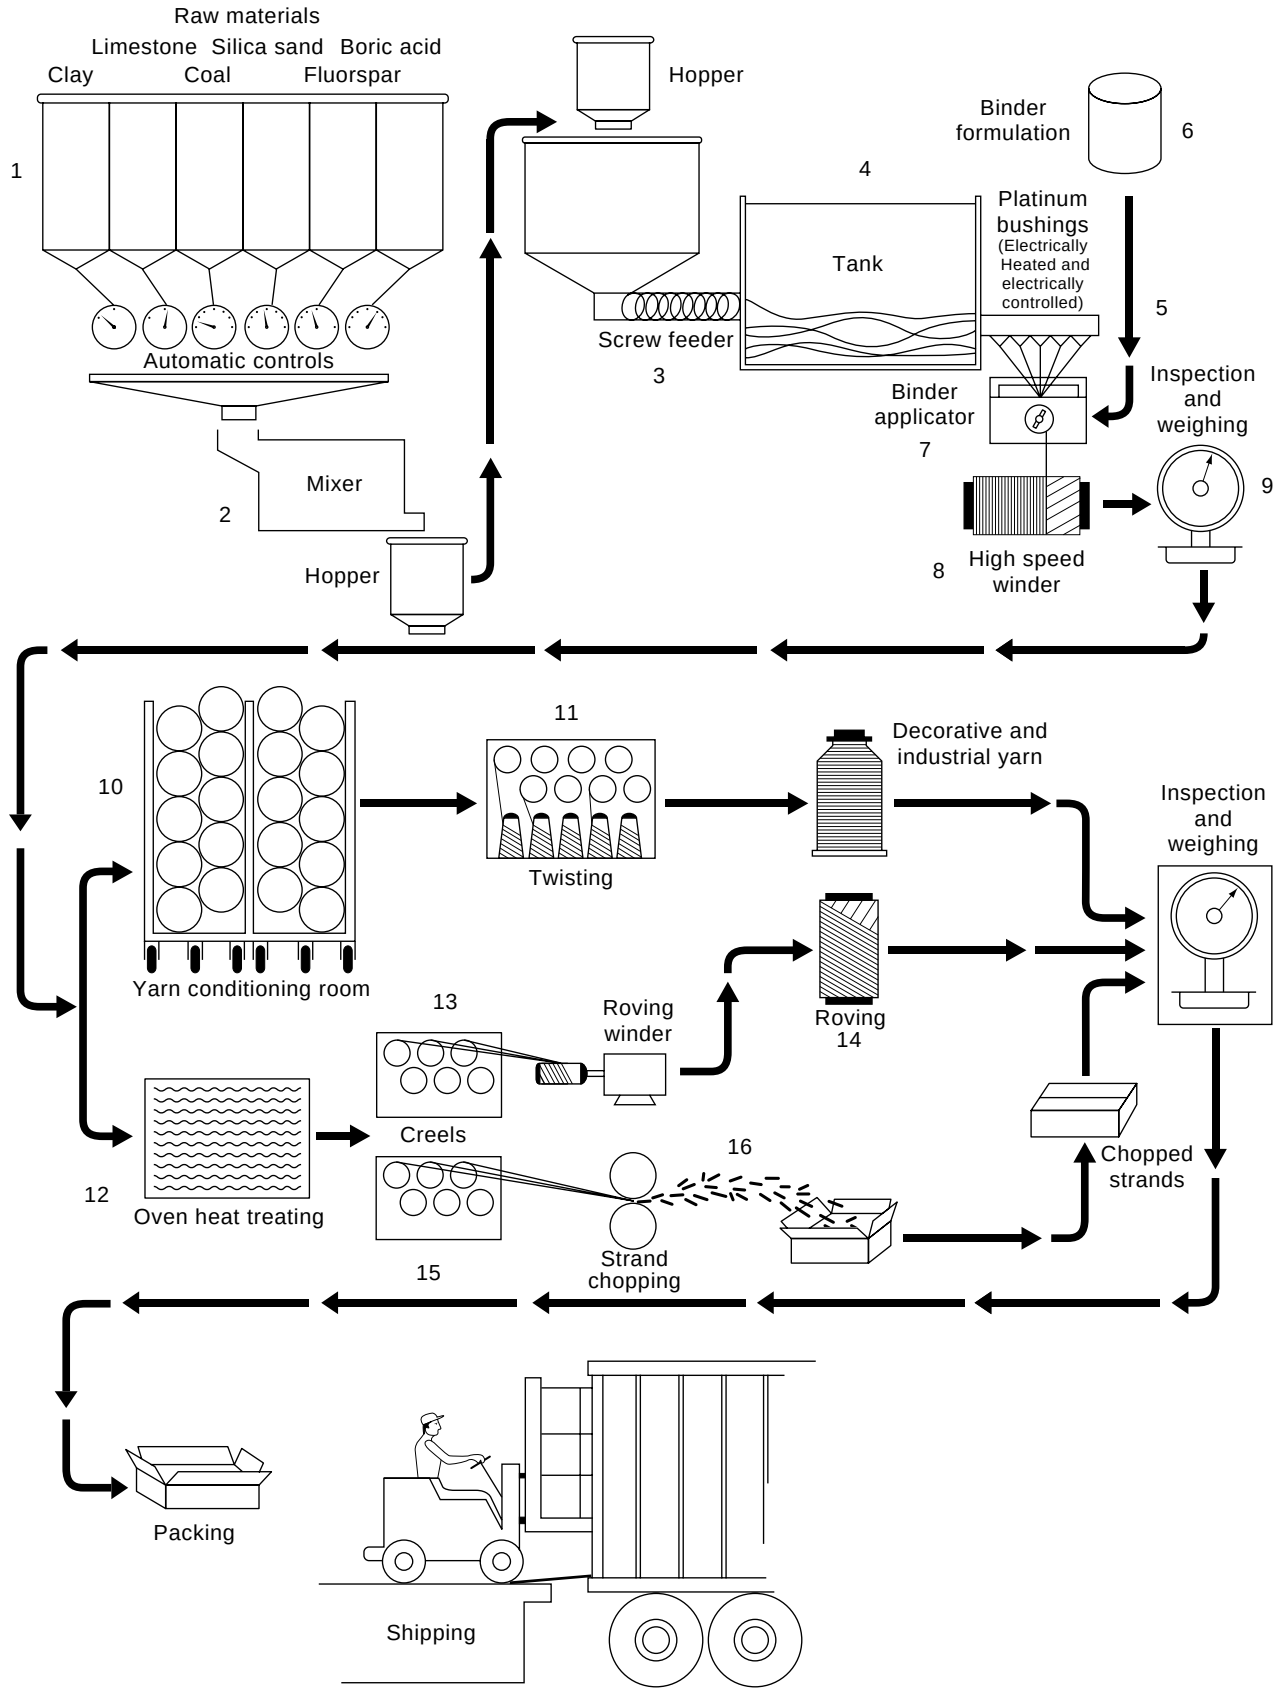

Fig. 1. Direct-melt process for producing fiber glass. Raw materials (1) are automatically weighed and batched to mixer (2) prior to passing through screw feeder (3) to the glass melting tank (4). The molten glass flows to forehearths (5), at the bottom of which are platinum-alloy bushings or spinners. The latter are electrically heated and carefully temperature-controlled. Formulated binder material (6) is applied to the newly formed filaments (7) prior to high-speed winding (8). After weighing and inspecting (9), the wound multi-filament (in the form of a strand) follows one of three paths in accordance with desired end product. In making decorative and industrial yarn, the package are placed in a conditioning room (10) prior to twisting (11). For the production of roving and chopped strand, the material from inspection operation (9) passes to an oven (12), where the filaments are heat-treated. This is followed by creeling (13) and roving winding (14) for production of roving. Following creeling (15), chopped strands (16) may also be made. There are several additional weighing and inspecting stations. (*PPG Industries.*)

The coarse primary rods then are filamentized by a high-temperature, high-velocity blast burner. The blown mass of filaments is collected on a conveyor belt and bonded together by an inert thermosetting resin in a manner which creates many tiny air spaces throughout the material. The bonding process may be modified to produce flexible blankets, rigid board, or special molded shapes, such as pipe insulation. Coatings, facings, or jackets usually are applied for reflective, vaporbarrier, or decorative purposes.

In another process (replacing the high-temperature blast-jet process in some areas), a stream of molten glass is directed onto a rapidly rotating wheel which contains holes in its periphery. Centrifugal force directs glass through each hole to create fibers. A third process involves conversion of 2-to-6-inch (5-to 15-centimeter) chopped strand and textile-type yarns into separate and random monofilaments by a garnetting machine.

Properties of Staple Fibers. Fiber diameters range from AAA to G (Table 2), with the largest production volume in the range C — G. Thermal conductivity of glass-fiber products is influenced by fiber diameter, density or compactness of the fiber mass, and temperature conditions. Generally, thermal conductivity ranges between 0.20 and 0.80 (Btu)(in.)/(hr)(ft^2)(°F). In metric units, this is: 0.029 and 0.115 watt/meter-Kelvin W/m · K.

Temperature of applications ranges between near absolute zero to 593 °C (1100 °F), or to the softening point of the glass. Unbonded mat is used at extreme temperature conditions, whereas standard bonded insulation covers the range of −40 to 232 °C (−40 to 450 °F). Fiberglass acoustical products are particularly good energy absorbers at the frequency levels of 500-2000 Hz. Fiber diameter, density, and method of mounting control the absorbing characteristics.

TABLE 2. CODING SYSTEM FOR FIBER GLASS DIAMETERS

Designation	Diameter $\times 10^{-5}$ in.
AAA	<3.0
AA	3.0–5.9
A	6.0–9.9
B	10.0–14.9
C	15.0–19.9
DE	23.0–27.9
G	35.0–39.9
H	40.0–44.9
K	50.0–54.9
P	70.0–74.9
Q	75.0–80.0
R	81.0–85.0
S	86.0–90.0
T	91.0–95.0
U	96.0–100.0

Note: To convert to microns (micrometers), multiply by 25.4×10^{-2}.

Glass fibers as used in lightwave communications are described under **Optical Fiber Systems**. See also Alphabetical Index.

FIBER-REINFORCED COMPOSITES. Many advances were made in the 1980s toward the design and application of metal and other composite structures. These materials usually offer large advantages in strength-to-weight and stiffness-to-weight ratios. Many composites have excellent temperature- and corrosion-resistance properties. Aluminum and graphite are among the favored materials for constructing composites. However, the technology has applied scores of materials — metals, fibers, polymers, etc. — in the search for better materials for specific applications. One of the earliest and still the most popular cellular structures for composite materials is the hexagonal honeycomb. Cell structures vary, but typically they measure from 1.5 to 25.5 mm (0.06 to 1 in.) across. As shown in Figure 1, several other shapes and contours are made. In addition to aluminum, metals commonly used include stainless steel, titanium, and nickel alloys. Reinforced plastics are also used, particularly for honeycomb. Aramid-reinforced epoxy, phenolic, and polyimide cores were recently introduced. These materials offer low coefficient of thermal expansion and good electric and thermal insulation. Glass-fiber reinforced phenolics are now frequently specified for heat resistance, while some carbon-fiber reinforced resins also match the strength of metal-core honeycomb. Density of composite materials ranges rather widely — typically from 16 to 880 kg/m^3 (1 to 55 lb/ft^3).

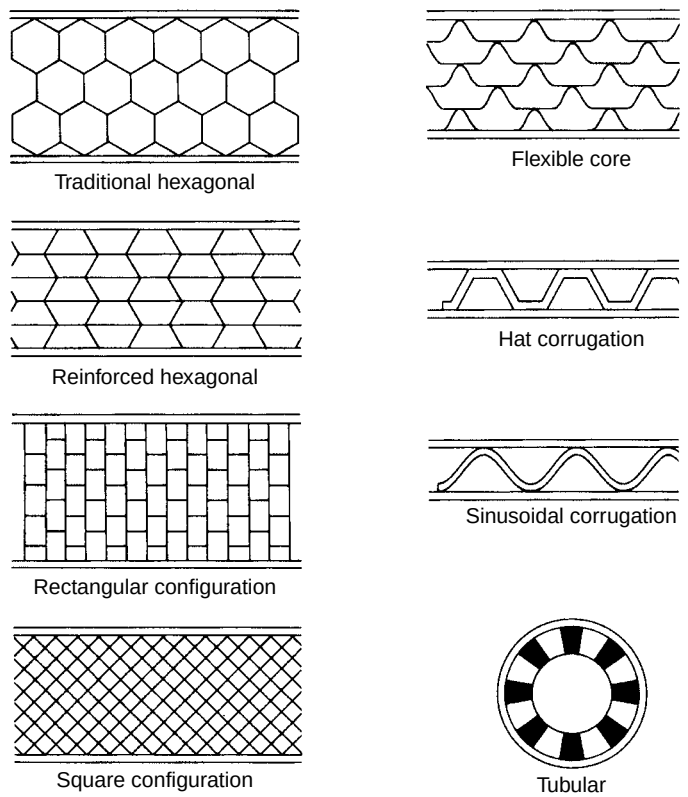

Fig. 1. Laminates (structural sandwiches) are made up of a core of either a solid material or a corrugated structure bonded between thin skins. The corrugated core often is filled with another lightweight material to provide added strength. The sinusoidal core and the "hat" core are two fundamental corrugated structures. For some applications, layers of core materials are stacked and bonded together to form even more complex structures, such as a honeycomb. Adhesive bonding is most commonly used, but some metal cores are welded or brazed. In structures from flat sheet, adhesive may be applied to adjoining surfaces in strips. Then the stack of laminates is stretched into an open cellular structure by pulling the plies apart. The basic honeycomb structure is difficult to form into complex shapes or contours. Overexpanding the plies to stretch the hexagonal cells into rectangles produces a variation on the honeycomb core that is more easily formed, but at the sacrifice of some shear properties. Other variations include the reinforced-hexagonal core, in which a flat sheet is inserted in the structure for added strength, but with an added weight penalty. The square-cell structure is usually produced by welding. The tubular structure is produced from corrugated sheet bonded to a flat sheet and wrapped around a mandrel. (*After Bittence*.)

Because composite materials technology is advancing so rapidly, and hence changing, it is not in order here to make a detailed probe. However,

the interested reader of this encyclopedia will find the references listed of considerable value in making an initial assessment of the field.

FIBERS. The field of fibers is an evolving one, with new technologies being developed constantly. With the increasing use of fibers in nontraditional textile applications, such as geotextiles, fiber-reinforced composites, specialty absorption media, and as materials of construction, new fiber types and new processing technologies can be anticipated.

A fiber may be described as a flexible, macroscopically homogeneous body having a high ratio of length to width and being small in cross section. Fibers, both natural and synthetic, are the fundamental structural components of yarn, thread, string, rope, paper, and woven and matted goods. Fibers usually exhibit considerable elasticity, the ability to return to their original dimension without permanent stretching. Most fibers tend to interlock or mechanically bond with other fibers, forming fiber matrices. Natural fibers are usually quite un-uniform; for example, cotton staple ranges from $\frac{1}{2}$ to $2\frac{1}{2}$ inches (1.3 to 6.4 centimeters) in length, with a diameter of about 1/1,000 inch (0.025 millimeter). Some synthetic fibers are made in the form of very thin filaments and thus may be quite uniform, with fiber length controlled and tailored for specific applications. Many materials required for the production of synthetic fibers are derived from petroleum and, along with synthetic plastics and resins, the synthetic fiber industry contributed importantly to the great growth of the chemical and petrochemical industries. To some extent, the essential raw materials for synthetic fibers are threatened because of competition for the same raw materials that are consumed for power in terms of fuels — both petroleum and natural gas.

The use of fibers dates back to antiquity. Very early uses (and still found among primitive peoples) are *tying* applications, using easily obtainable fibers from plants. Fibers have been used for centuries for making rough cordage, huts, and rope suspension bridges. Broomcorn and broomroot fibers have long been used for what might be termed *brush* applications. Straw, bamboo, rattan, and palm leaves were among the early *plaiting* and *rough-weaving fibers* for use in furniture making and basketry. Of course, they are still extensively used in various parts of the world for these purposes. The use of various reeds, husks, and grasses as *filling fibers* is very old, but large tonnages of such fibers still are used for packing materials, upholstery padding, and like applications.

The use of fibers in nonwoven sheet-like products is quite old, although there has been a resurgence of interest in so-called nonwovens during recent years. Felts, paper, and, more recently, some of the nonwoven disposable garments and products, notably for hospital use, are representative of the use of fibers for what might be termed *matting* and webbing applications. But by far the most important use of fibers, and the application most often visualized in connection with their use, is for the manufacture of knitted and woven textile fabrics and products. Spinning of the fibers to make yarn increases the utility of fibers for uses that far exceeded the imagination of those persons who first applied fibers in their cruder forms.

Although fibers can be classified in numerous ways, in terms of present-day technology, they are fundamentally classified as (1) natural fibers, and (2) synthetic fibers. The principal natural fibers are cotton, wool, and, to a much lesser extent, silk, flax, and mohair. Synthetic fibers have made inroads into the use of all natural fibers, but the greatest impact has occurred in connection with the latter three fibers. Cotton continues to be a major textile fiber, measured in terms of billions of pounds used per year. Cotton is one of the most versatile of all fibers and blends well with synthetics. This is also true of wool, but to a somewhat lesser extent. See also **Cotton (Gossypium Species Malvaceae** and **Flax (Linum Usitatissimum; Linaceae)**.

Synthetic Fibers. Introduced in 1910 as a substitute for silk, rayon was the first artificial or synthetic fiber. Rayon, of course, differs completely in chemical constitution from silk. Rayon typifies most reconstituted or synthetic fibers, which perform almost as well and, in a number of respects, far better than their natural "counterparts." Some of the more recently developed synthetic fibers have little if any resemblance to naturally available fibers and thus entirely new types of end-products with previously unobtainable end-qualities are available.

It is interesting to note that some authorities define a synthetic fiber as a "noncellulosic fiber of synthetic origin," a definition which excludes rayon and acetate. Other authorities, however, include rayon and acetate, along with nylons, polyesters, acrylics, and others, in the full spectrum of synthetic fibers. The reasoning behind the fine distinction is that, with cellulose-derived synthetics, one commences with a naturally fibrous material and grossly modifies it, whereas with most other synthetics, the starting materials are strictly chemicals that bear no relationship whatever to a fibrous structure, many of the starting ingredients actually being in the gaseous or liquid phase.

In classifying synthetic fibers, there is also a narrow, twilight zone between fibers and elastomers. There are elastomers with fiber-like qualities; and vice versa. For example, spandex is a fiber with rubber-like qualities. See also **Elastomers**.

Particularly in the period between the late 1930s and late 1950s, there was a vigorous development of new and different synthetic fibers, largely stemming from the research efforts of competing firms. Much of the technology was well guarded and there was an overwhelming tendency to give all new fibers tradenames rather than generic designations. This created much confusion, particularly in the marketplace. Some of the former tradenames were lost because they were widely and variously used and ultimately became the generic term for a class of fibers. As a tool for obtaining clarification, and for protecting buyers of various synthetic fibers, the U.S. Congress passed the Textile Fiber Products Identification Act, which is administered by the U.S. Federal Trade Commission. The principal synthetic fibers as so defined are listed in Table 1. For more complete definitions, refer to ASTM Standards on Textile Materials.

Many textile products combine the advantageous physical and chemical properties of two or more fibers (synthetic or natural). Careful preblending operations are usually required.

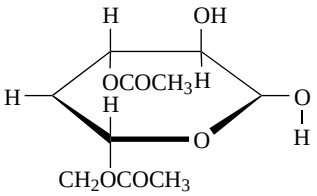
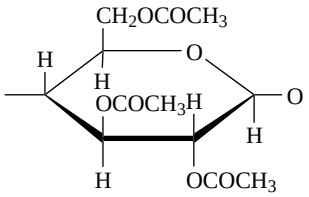
ACETATE FIBERS

A manufactured fiber in which the fiber-forming substance is cellulose acetate[CAS:9004-35-7]. Where not less than 92% of the hydroxyl groups are acetylated, the term *triacetate* may be used as a generic description of the fiber. A portion of the molecule may appear as:



(acetate)



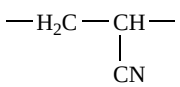
(triacetate)

Specific gravity: 1.3–1.32
Moisture regain: 3.2% (triacetate); 6.3–6.5% (acetate)
Tensile strength: $18–22 \times 10^3$ psi (124–152 MPa) (triacetate)
$20–24 \times 10^3$ psi (138–166 MPa) (acetate)
Excellent to impervious to aging. Good resistance to mildew discoloration and sunlight (acetate), although there may be some loss of strength from long exposure to sunlight. Triacetate has poor resistance to sunlight. Fair resistance to abrasion.
Attacked by strong oxidizing agents. Resists common solvents, normal hypochlorite, peroxide bleaching. Dissolves or swells in acetone[CAS:67-64-1], ketones, trichloroethylene[CAS:79-01-6], concentrated and glacial acetic acid[CAS:64-19-7], and methylene chloride[CAS:7″-09-2].
Triacetate[CAS:2140-49-0] does not stick when ironed at cotton setting temperature, 450 °F (232 °C). Melts at 572 °F (301 °C). Acetate sticks at 350–375 °F (177–191 °C). Softens at 400–445 °F (204–230 °C). Melts at 500 °F (260 °C).
Dyes: Dispersed and developed dyes are commonly used. Acid dyes are used for printing. Solution dyed available. See also **Dyes: Application and Evaluation.**
Types available:
Triacetate (filament)
Acetate (filament and staple)

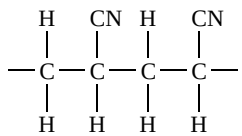
See also **Fibers (Acetate).**

ACRYLIC FIBERS

A manufactured fiber in which the fiber-forming substance is any long-chain synthetic polymer composed of at least 85% by weight of acrylonitrile units:



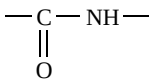
A portion of the molecule may appear as:



Specific gravity: 1.16–1.18
Moisture regain: 1.0–2.5%
Tensile strength: $30–54 \times 10^3$ psi (207–373 MPa)
Excellent resistance to mildew and aging. Good resistance to sunlight and abrasion.
Good resistance to bleaches and common solvents.
Generally good resistance to mineral acids and weak alkalis.*
Safe ironing temperature up to 300 °F (150 °C).*
Does not support combustion.
Dyes: Disperse and cationic.*
Principal brands:
Acrilan®, Monsanto (staple)
Creslan®, American Cyanamid (staple and tow)
Mannacryl®, Mann Industries (staple, tow, and pulp)
See also **Fibers (Acrylic)**

ARAMID FIBERS

A manufactured fiber in which the fiber-forming substance is a long-chain synthetic polyamide in which at least 85% of the amide linkages are attached directly to two aromatic rings. Amide linkage:



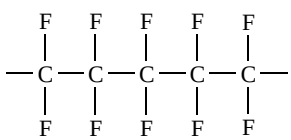
Specific gravity: 1.38–1.44
Moisture regain: 4.5–7% (at 55% RH)
Tensile strength: $90–400 \times 10^3$ psi (621–2760 MPa)
Excellent resistance to mildew and aging. Prolonged exposure to sunlight causes deterioration, but fibers are self-screening. Good abrasion resistance.*
Some are degraded by bleaching; others are not affected. No degradation in solvents, except slight loss of strength from exposure to sodium chlorite.*
Unaffected by most acids, except some strength loss after long exposure to hydrochloric[CAS:7647-01-0], hydrobromic[CAS:10035-10-6], nitric[CAS:7697-37-2], and sulfuric acid[CAS:7664-93-9]. Generally good resistance to alkalis.*
Difficult to ignite — does not propagate flame — does not melt. Decomposition temperature is from 700 to 930 °F (371 to 499 °C).*
Dyes: Industrial yarn is nondyeable. Staple is dyeable with cationic dyes.
Principal brands:
Kevlar®, DuPont (filament)
Nomex®, DuPont (staple, tow and filament)

CARBON FIBERS

A manufactured fiber made by pyrolysis of an organic precursor — rayon, polyacrylonitrile[CAS:25014-41-9], or pitch in an inert atmosphere.
Specific gravity: 1.77 (1.96 for high-modulus)
Moisture regain: 0
Tensile strength: 515×10^3 psi (3554 MPa)
360×10^3 psi (2484 MPa)
270×10^3 psi (1863 MPa)
Does not melt. Oxidizes slowly in air at temperatures above 600 °F (316 °C).
Cannot be dyed.
Excellent resistance to acids and alkalies, even at high concentration and temperature.
Strong oxidizers will degrade fiber.
Inert to all known solvents, but poor resistance to hypochlorite.
Excellent resistance to mildew, aging, and sunlight. Poor resistance to abrasion.
Supplier:
Celion®, BASF Structural Materials (high-strength, high-modulus, and ultrahigh-modulus fibers).

FLUOROCARBON FIBERS

Fiber formed of long-chain carbon molecules whose available bonds are saturated with fluorine. A portion of the molecule may appear as:



Specific gravity: 0.8–2.2
Moisture regain: 0
Tensile strength: $25–115 \times 10^3$ psi (173–794 MPa)
Good to excellent resistance to mildew, aging, sunlight, and abrasion.
Essentially inert to bleaches and solvents except for alkali metals at high temperature and/or pressure. Fluorine gas and chlorine trifluoride[CAS:7790-91-2] react with fibers at high pressures and temperatures.*
Essentially inert to acids and alkalis.
Very heat resistant. Usually can be safely handled from −350 to +550 °F (−212 to +288 °C).* Melts between 550 and 620 °F (288 and 327 °C).*

(*continued*)

Dyes: Some cannot be dyed; others can be pigmented and dyed with selected solvent system.
Principal brands:
Gore-Tex®, W.L. Gore (expanded PTFE staple, filament, tow, and slit film-RT)
Teflon® DuPont (TFE multifilament, staple, tow and flock; FEP monofilament)

GLASS FIBERS

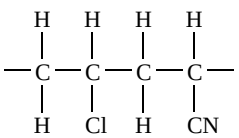
A manufactured fiber in which the fiber-forming substance is glass.
Specific gravity: 2.48–2.69
Moisture regain: None
Tensile strength: $313–700 \times 10^3$ psi (2160–4830 MPa)
Not attacked by mildew, although binder may be affected by it. Excellent resistance to aging and sunlight.
Unaffected by bleaches and solvents.
Resists most acids and alkalis.
Nonburning. Generally holds 75% tensility up to 650 °F (343 °C). Softens between 1560 and 1778 °F (843 and 970 °C). Melts at 2720 °F (1493 °C).
Dyes: Resin-bonded pigment systems. Vat, acid, or chrome dyes will tint.
Available from numerous manufacturers.

LYOCELL FIBERS

A manufactured fiber composed of solvent spun cellulose.
Specific gravity: 1.56
Moisture regain: 11.5%
Tensile strength: Not available
Attacked by mildew, but has good resistance to aging, sunlight, and abrasion.
Attacked by strong oxidizing agents. Not damaged by bleaches.
Generally insoluble in common organic solvents.
Hot dilute or cold concentrated acids disintegrate the fiber, similar to cotton. Strong alkaline solutions cause swelling and reduce strength. Can be mercerized.
Does not melt. Loses strength at about 300 °F (572 °F) and begins to decompose at about 350 °F (171 °C) under extended periods of exposure.
May be dyed with all classes of dyes normally used for dyeing cellulosic fibers.
Supplied by:
Tencel®, Courtaulds

MODACRYLIC FIBERS

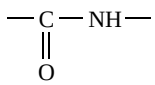
A manufactured fiber in which, when not qualified as rubber or anidex, the fiber-forming substance is any long-chain synthetic polymer composed of less than 85%, but at least 35% by weight of acrylonitrile units. A portion of the molecule may appear as:



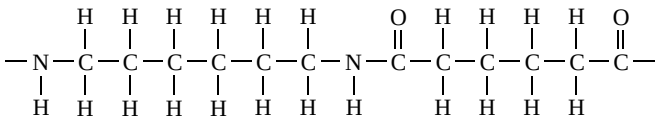
Specific gravity: 1.35–1.37
Moisture regain: 2.5–3.0%
Tensile strength: $29–47 \times 10^3$ psi (200–324 MPa)
Good to excellent resistance to mildew, aging, and sunlight. Good resistance to abrasion.
Good resistance to bleaches, dry-cleaning fluids, and most common solvents. Dissolves in warm acetone and acrylic-type solvents.
Resistant to most acids and good resistance to weak alkalis; some discoloration may result.*
Boiling-water shrinkage, about 1%. Good resistance to shrinkage in dry heat, with about 5% shrinkage at 390 °F (200 °C). Pressure and heat at 300 °F + (150 °C+) may cause stiffening and discoloration.*
Does not support combustion.
Dyes: Neutral-premetalized, cationic (basic), and disperse.*
Principal brands:
SEF, Monsanto (staple)

NYLON FIBERS

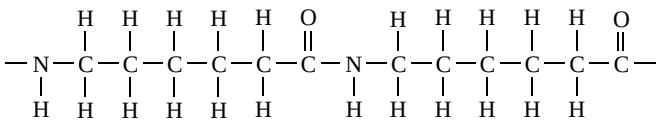
A manufactured fiber in which the fiber-forming substance is a long-chain synthetic polyamide in which less than 85% of the amide linkages are attached to two aromatic rings. Amide linkage:



A portion of the Nylon 6,6 molecule, based upon hexamethylene diamine[CAS:124-09-4]and adipic acid[CAS:124-04-9], may appear as:



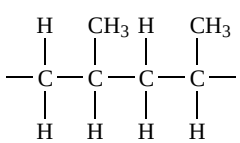
A portion of the Nylon 6 molecule, based upon caprolactam, may appear as:



Specific gravity: 1.03–1.14 (most = 1.14)
Moisture regain: 2.8–5%*
Tensile strength: $40–134 \times 10^3$ psi (276–925 MPa)*
Excellent resistance to mildew, aging, and good-to-excellent resistance to abrasion. Prolonged exposure to sunlight causes some deterioration.
Excellent resistance to bleaches and other oxidizing agents. Generally insoluble in most organic solvents except some phenolic compounds.
Strong oxidizing agents and mineral acids may cause degradation of some brands. However, generally unaffected by most mineral acids, except when hot. Dissolves with partial decomposition in concentrated solutions of hydrochloric, sulfuric, and nitric acids.* Substantially inert in alkalis.
Sticking temperature is about 445 °F (229 °C).* Melts between 480 and 525 °F (249 and 274 °C).* Some yellow slightly if held at 300 °F (150 °C) for several hours. Decomposes between 600 and 730 °F (316 and 388 °C).*
Dyes: Has marked affinity for all types of dyestuffs, including pigment, direct, acid, premetalized acid, disperse, chrome, and vat colors, including complex types.*
Principal brands:
Nylon 6, DuPont and others (staple, monofilament and filament-RT and -HT, staple and tow)
Nylon 6,6, DuPont and others (staple and tow; monofilament and filament-RT; and filament-HT)

See also **Nylon**
OLEFIN FIBERS

A manufactured fiber in which the fiber-forming substance is any long-chain synthetic polymer composed of at least 85% by weight of ethylene, propylene, or other olefin units. A portion of the molecule may appear as:



(Polypropylene)

Specific gravity: 0.9–0.96.
Moisture regain: Negligible (polyethylene); 0.01–0.1% (polypropylene)
Tensile strength: $11–90 \times 10^3$ psi (76–621 MPa)*
Not attacked by mildew. Good to excellent resistance to sunlight, abrasion, and aging.

Resistance to bleaches and most solvents, but some swelling in chlorinated hydrocarbons at room temperature and dissolves at 160 °F (71 °C) and higher.*
Excellent resistance to acids and alkalis, with exception of oxidizing agents, such as chlorosulfonic acid and concentrated nitric acid.
Softens at 225–235 °F (107–113 °C) (polyethylene): at 285–330 °F (141–166 °C) (polypropylene).
Melts at 230–250 °F (110–121 °C) (polyethylene); at 320–350 °F (160–177 °C) (polypropylene).
Dyes: Traditionally fibers are pigmented during manufacture, but some can be dyed with disperse, acid, and chelating dyes and certain vats, sulfurs, and azoics.
Types available:
Polyethylene, Hercules (monofilament)
Herculon®, Hercules (staple, bulk filament)
Marves®, Alpha®, Phillips (staple, tow, multifilament)
Essera®, Amoco XXV®, Marquesa®, Lana®, Palton III, Amoco (staple, tow, multifilament)
Spectra 900 and 1000®, Allied (various types)
Fibrilon®, Synthetic Industries (fibrillated and monofilament)

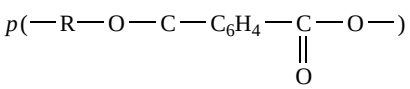
See also **Olein Fibers.**

POLYBENZIMIDAZOLE FIBERS

A manufactured fiber in which the polymer is a sulfonated poly(2,2′-*m*-phenylene-5,5′-dibenzimidazole).
Specific gravity: 1.43
Moisture regain: 15–20%
Tensile strength: 50×10^3 psi (345 MPa)
Will not ignite. Does not melt. Decomposes in air at 860 °F (460 °C). Retains fiber integrity and suppleness upon flame exposure. High char yield.
Excellent resistance to most acids and alkalies. Some loss of strength in strong alkalis at elevated temperature. Excellent resistance to organic solvents. Unaffected by most bleaches and solvents.
Natural fiber color is gold. Dyeable to dark shades with basic dyes following caustic treatment.
Good resistance to mildew and aging. Prolonged exposure to sunlight causes darkening and some loss of tensile strength. Good abrasion resistance.
Principal brands:
PBI®, Hoechst Celanese (staple)

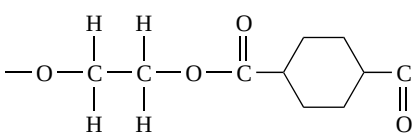
POLYESTER FIBERS

A manufactured fiber in which the fiber-forming substance is any long-chain synthetic polymer composed of at least 85% by weight of an ester of a substituted aromatic carboxylic acid, including but not restricted to substituted terephthalate units:



and parasubstituted hydroxybenzoate units:

A portion of the molecule may appear as

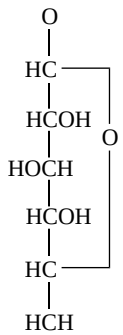


Specific gravity: 1.34–1.39 (most = 1.38)
Moisture regain: 0.4%
Tensile strength: $33–165 \times 10^3$ psi (228–1139 MPa)*
Good to excellent resistance to mildew and sunlight, although prolonged exposure to full sunlight degrades some brands (strength loss). Abrasion resistance ranges from good to excellent.
Good to excellent resistance to bleaches, soaps, synthetic detergents, dry-cleaning agents, sea water, and perspiration. May be soluble in some phenolic compounds.
Sticking temperature is 440–445 °F (227–230 °C). Melts between 480–500 °F (249–260 °C).*
Good resistance to most mineral acids. Dissolves with partial decomposition in concentrated sulfuric acid. Good resistance to weak alkalis. Moderate resistance to strong alkalis.*
Dyes: Disperse, azoic, and cationic dyes.*
Principal brands:
A.C.E.®, Compet®, Allied (filament)
Dacron®, DuPont (staple and tow; partially oriented filament; filament-RT; filament-HT)
Fortrel®, Fiber Industries Div. Celanese (staple, RT AND HT; filament, RT and HT)
Kodel®, Eastman (staple)
Polyester, BASF (filament)
Trevira®, Hoechst Celanese (staple and filament)

See also **Polyester Fibers.**

RAYON FIBERS

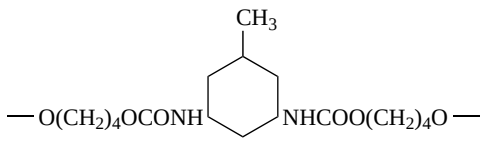
A manufactured fiber composed of regenerated cellulose, as well as manufactured fibers composed of regenerated cellulose in which substituents have replaced not more than 15% of the hydrogens of the hydroxyl groups. A portion of the molecule may appear as:



Specific gravity: 1.46–1.54
Moisture regain: 11–13%
Tensile strength: $28–66 \times 10^3$ psi (193–455 MPa)*
Attacked by mildew. Resistant or stable to aging.* Mostly good resistance to sunlight and abrasion, but long exposure may yellow some intermediate rayons.*
Not affected by solvents. Insoluble in common organic solvents. Some attacked by strong oxidizing agents, but generally not damaged by hypochlorite or peroxide.*
Most rayons behave to acids much as cotton. Hot dilute or cold concentrated acids cause disintegration of fibers. Strong alkaline solutions cause swelling and reduce strength.*
Fibers do not melt, but may lose strength above 300 °F (150 °C) and decompose between 350 and 464 °F (177 and 240 °C).*
Dyes: Direct, vat, fiber-reactive, sulfur and pigment.*
Principal types and brands: Cuprammonium, available from several sources (filament).
Fibro®, Courtaulds (filament)
Rayon, North American Rayon Corp. (filament)
Saran®, Pittsfield Weaving (monofilament)

SPANDEX FIBERS

A manufactured fiber in which the fiber-forming substance is a long-chain synthetic polymer comprised of at least 85% of a segmented polyurethane. A portion of the molecule may appear as:



Specific gravity: 1.2
Moisture regain: <1.0–1.3
Tensile strength: $11–15 \times 10^3$ psi (76–104 MPa)
Good to excellent resistance to mildew, aging, sunlight, and abrasion.

TABLE 1. (*Continued*)

Good resistance to deterioration by bleaches, but some discolored slightly by hypochlorite bleaches. Resistant to solvents, including dry-cleaning fluids, and oils, except glycols.*
Good resistance to mild acids and alkalis, but may be degraded by strong acids and alkalis at high temperatures. Some are slightly yellowed by dilute hydrochloric and sulfuric acids.*
Sticking point from 347 to 420 °F (75 to 216 °C).* Melts at 511–518 °F (267–269 °C).*
Dyes: Good affinity for most classes of dyes, but disperse, acid, and premetalized dyes are generally preferred.*
Principal brands: Glospan/Cleerspan®, Globe (multifilament) Lycra®, DuPont (coalesced monofilament)

SULFUR FIBERS

Fiber-forming substance is a long-chain synthetic polysulfide with at least 85% of the sulfide linkages attached directly to two aromatic rings.
Specific gravity: 1.37
Moisture regain: 0.6%
Tensile strength: $35–40 \times 10^3$ psi (242–276 MPa)
Outstanding resistance to heat. Retains more than 70% of original strength after exposure to air at 400 °F (204 °C) for 5000 hours.
Excellent resistance to acids and alkalies, except hot, concentrated sulfuric acid and concentrated nitric acid.
Resistant to bleaches and solvents.
Nondyeable.
Excellent resistance to mildew, sunlight, aging, and abrasion.
Principal brands:
Ryton® Phillips (staple)

Characteristics of Major Natural Fibers

COTTON

General formula, $(C_6H_{10}O_5)_x$, Chemical composition is cellulose.
Specific gravity: 1.54
Moisture regain: 7.0–8.5%
Cotton is attacked by cold concentrated acids and by hot dilute acids. Alkalis cause mercerization, but without damage. Cotton is quite resistant to most solvents.
Cotton fabrics have an excellent hand, good abrasion resistance, excellent pilling resistance, excellent stability to repeated launderings (if preshrunk), fair sunlight resistance, excellent colorfastness, good wash and wear performance (if resin-treated), and good wrinkle resistance (if resin-treated).
Safe ironing temperature: 425 °F (219 °C)
Dyes used: Direct, vat, azoic, basic, mordant, pigment, sulfur, and fiber-reactive.

WOOL

General formula $(C_{42}H_{157}O_{15}N_5S)_x$. Chemical composition is keratin.
Specific gravity: 1.32
Moisture regain: 11–17%
Tensile strength: $17–29 \times 10^3$ psi (117–200 MPa)
Wool shows marked effects of thermal degradation above 212 °F (100 °C). Scorches at 400 °F (204 °C): chars at 570 °F (299 °C).
Wool is destroyed by hot sulfuric acid; otherwise it is quite resistant to acids. Strong alkalis destroy the material; it is attacked by weak alkalis. Wool is quite resistant to most solvents.
Tensile strength: $60–120 \times 10^3$ psi (414–828 MPa)
Cotton fibers are quite resistant to thermal degradation. After about 5 hours at 250 °F (121 °C), material yellows. Decomposes above 300 °F (150 °C).
Wool fabrics have an excellent hand, fair abrasion resistance (but good in carpets), good pilling resistance (pills form, but tend to break off), poor stability to repeated launderings, good sunlight resistance, good colorfastness, poor wash and wear performance, and good wrinkle resistance.
Safe ironing temperature: 300 °F (149 °C)
Dyes used: Acid, milling, chrome, mordant, vat, and indigo.

SILK

Silk is comprised essentially of the protein fibroin.
Silk fabrics have an excellent hand, fair abrasion resistance, good pilling resistance, good stability to repeated launderings, poor sunlight resistance, good colorfastness, poor wash and wear performance, and good wrinkle resistance.
Safe iron temperature: 300 °F (149 °C)

FLAX

A bast fiber.
Flax fabrics (linen) have an excellent hand, fair abrasion resistance, fair pilling resistance, good stability to repeated launderings, fair sunlight resistance, excellent colorfastness, very poor wash and wear performance, and poor wrinkle resistance.
Safe ironing temperature: 450 °F (232 °C).

Note: Unless otherwise noted, moisture regain is stated for a relative humidity of 65% at 8 °F (21.1 °C). RT = regular tenacity: HT = high tenacity; IT = intermediate tenacity.
*indicates variation of this property with particular brand of fiber.

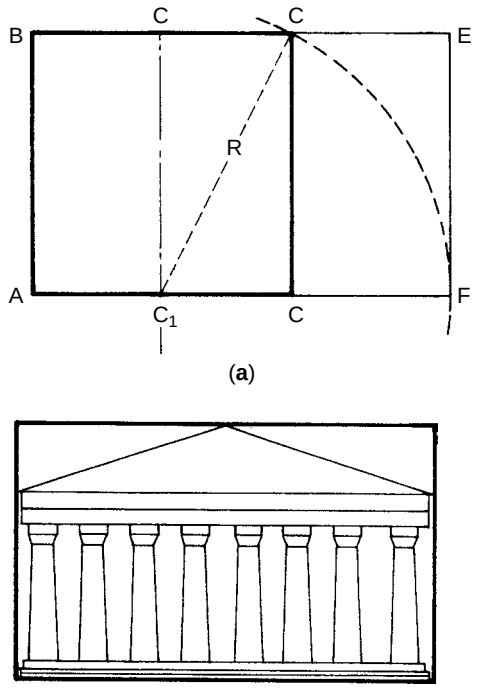
FIBONACCI NUMBERS. Medieval investigator, Leonardo ("Fibonacci") da Pisa proposed a sequence of numbers, commencing with 1, adding 1 to itself, to yield 2, and thereafter adding the last two numbers in the series to yield the next number in the series. Thus, 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89 ··· etc. Although an apparent curiosity, Fibonacci numbers bear a surprising relationship to botany and classical art. Examples of Fibonacci numbers in nature include the spirals of tiny florets found in the core of daisy blossoms. There are sets of clockwise and counterclockwise spirals. Each set has a predetermined number of spirals. In daisies, there are 21 clockwise and 34 counterclockwise, the 21:34 ratio being made up of two adjacent Fibonacci numbers. Opposing spirals in pine-cone scales bear a 5:8 ratio. The leaves of several trees and the bumps on pineapples bear an 8:13 ratio. After the number 3 in the Fibonacci series, adjacent numbers have a ratio of approximately 1:1.6 ($\frac{21}{13} = 1.6154$; $\frac{34}{21} = 1.6190$; $\frac{55}{34} = 1.6176 \cdots$ etc.). This is essentially the value of the Golden Ratio or Golden Section (1:1.618), which occurs in circles, decagons and pentagons. The best known example of the Golden Ratio is the Golden Rectangle, the sides of which bear this ratio. See Fig. 1. The Parthenon at Athens is patterned in accordance with the Golden Rectangle, but it is doubtful that the builders at that time were consciously aware of the Golden Ratio. See also **Number Theory**.

FIBRIL. A minute thread-like structure in a cell, also the smaller components of the intercellular white fibers of connective tissue.

Fibrils occur near the surface of smooth muscle cells and connective tissue cells (border or myoglia fibrils and fibroglaia fibrils, respectively) and in fully differentiated muscle and nerve cells (myofibrils and neurofibrils, respectively).

FIBRILLATION. Fibrillation is a mode of electrical activity in the heart muscle, alternative to the usual once-a-second mode paced from the heart's sinoatrial node. There are two kinds. ***Atrial*** fibrillation is restricted to the upper chambers of the heart. While it is not immediately life-threatening, it does make ventricular pumping rapid and irregular, resulting in fatigue and light-headedness, and so disables the patient for exertion. By loosening particles of atherosclerotic plaque, it also dramatically



(**a**)

(**b**)

Fig. 1. Golden rectangle. (**a**) To construct a golden rectangle, commence with square $ABCD$. Divide square into two equal halves on either side of center line CC_1. Using circle radius R, extend portion of circle to intersect extension of AD at point F. Resulting rectangle $ABEF$ is a golden rectangle with $AB : AF$ 1:1.6. Rectangle $CDEF$ also is a golden triangle. (**b**) The facade of the Parthenon at Athens fits almost perfectly inside a golden rectangle.

increases the risk of stroke. It can usually be controlled surgically and/or by prescription drugs such as digoxin. In refractory instances, a single strong electrical shock ("cardioversion") often permanently restores normal beating. The other kind is ***ventricular*** fibrillation, affecting the thick-walled pumping chambers of the heart. During ventricular fibrillation blood pressure plummets, the brain is deprived of oxygenated blood and suffers irreversible damage within minutes, and sudden death is the result. Other than prevention, the only known therapy for this kind of fibrillation is immediate strong electrical shock to re-synchronize the ventricles. This can be done by using a device having a set of electrodes known as a defibrillator.

Mechanism

In the 1970s almost all research into the mechanisms of fibrillation focused on the role of inhomogeneities, e.g., patches of muscle deprived of adequate blood circulation. It was believed that more inhomogeneities imply more risk of fibrillation, and that without any, risk would be negligible. The fundamental mechanism was thought to be irregular circulation of electrical activation waves between and around inhomogeneities, and/or their fragmentation into "multiple wandering wavelets." This vision seems well confirmed even in perfectly healthy ***atria***, which have a complicated architecture including extensive inhomogeneities. The electrocardiogram shows little regularity during atrial fibrillation.

However un-diseased ***ventricles*** are more uniform. In the 1980s it was found that the impression of utterly irregular activity somewhat misleads. Ventricular fibrillation has a rather regular periodicity around 10 Hz, particularly if attention is confined to any one point in the heart. But because its period differs a little from place to place, this periodicity is not synchronous everywhere (which is half the reason the muscle cannot pump blood during fibrillation, the other half being that the period is too short). So when the electrocardiogram sums over the whole heart, it presents only low-amplitude irregularity. Attempts to interpret these ***temporal*** characteristics in terms of "low-dimensional chaos" led to changing "low" to "high", which is seldom distinguishable from randomness. A focus on the ***spatial*** structure of fibrillation was more productive.

Increasing availability of faster digital computers allowed electrophysiologists to explore the implications of their ionic models for the electrical mechanisms of the cardiac cell membrane. It was already clear that these partial differential equations produced action potentials resembling those seen in heart muscle, and that they propagate 1-dimensionally (along a simulated muscle fiber) much as in the laboratory. ***Would*** anything new arise when the context is expanded to two dimensions or three? In two dimensions these models revealed a vortex-like action potential called the "rotor". Its rotation period is close to the dominant periodicity observed during fibrillation. It moves around erratically and sometimes spawns new rotors.

By attaching large arrays of electrodes on the heart surface to computers, electrophysiologists were able to observe electrical patterns during fibrillation. They observed rotors moving around. In the 1990's these methods were improved and supplemented by video cameras observing voltage-modulated fluorescence of cardiac cell membranes. These higher-resolution movies confirmed the impression of rotors, but showed that individual rotors seldom last even as long as one or two turns, and that more complex electrical patterns develop in which no rotors are seen, but the periodicity remains about the same.

In the 1990s numerical models were pursued to three dimensions. It turned out that the "rotor" is only a cross-section of a "vortex filament" where it emerges to the surface of the heart wall. Within the wall, these filaments move irregularly. If they tend to lie parallel to the surfaces within the wall, no rotors are seen on the surface, but excitation erupts to the surface at the same characteristic period, while the muscle incoherently attempts to contract at that short period. Recent observations with computer-driven fluorescence cameras seem to be disclosing the reality of these recently-appreciated implications of well-established ionic models of cardiac cell membrane excitability.

Treatment

What are the implications for medical practice? One is that previously dominant certainties are not the whole story. Pharmaceutical modifications of the cell membrane that took no account of the foregoing killed more patients than they saved, up to about 1990 (Moore, 1995). However beta-blocking drugs (that minimize the impact of the sympathetic nervous system on the ventricular muscle) caused no such trouble and remain in wide use. Today medical practice is shifting from drugs toward implanted electronic defibrillators for patients at particular risk of ventricular fibrillation. Whether their design can be enhanced (or other pharmaceuticals can be designed), by reference to recent discoveries about rotor dynamics remains to be seen.

FIBRIN. See **Blood**.

FIBRINOGEN. See **Protein**.

FIBROMA. A benign tumor of fibrous or connective tissue, a fibroid tumor may occur in various parts of the body but, it is most often found in the uterus. There, in combination to a varying degree with proliferated muscle fibers, they constitute the fibromyoma, which may grow to great size and produce pressure symptoms and abnormal bleeding. Uterine fibroids are the most common cause for removal of the uterus.

FICTILE. Descriptive of certain molecules which have no permanent structure but are constantly changing their shapes and arrangements. An

example is the metal carbonyl $Fe_3(CO)_{12}$, in which, according to F. Albert Cotton, originator of the term, "carbonyl groups readily move from one iron atom to another through the rapid formation and dissolution of carbonyl bridges between iron atoms."

FICTITIOUS. In cartography, pertaining to or measured from an arbitrary reference line as in fictitious equator, fictitious latitude, fictitious longitude. Transverse, oblique, and grid map projections are examples of fictitious projections.

FICTITIOUS YEAR. The period between successive returns of the sun to a sidereal hour angle of 80° (about January 1). Also called *Besselian year*, or *Bessel fictitious year*. The length of the fictitious year is the same as that of the tropical year, since both are based upon the position of the sun with respect to the vernal equinox. See also **Time**.

FIDELITY (Communications). The degree with which a system, or a portion of a system, accurately reproduces at its output the essential characteristics of the signal impressed upon its input. The term is usually applied to an amplifier or communications circuit to indicate its ability to reproduce the original signal without distortion. A high-fidelity audio amplifier will amplify all audio frequencies equally, whereas a poor-quality amplifier will badly attenuate certain frequencies, usually the low and high frequencies, while passing the middle audio range. Many radio receivers have fidelity controls. These are in the intermediate frequency circuits and have the effect of broadening the pass band of such circuits. Most of the loss of the high frequencies in the radio is due to the various selective circuits cutting out the higher sideband frequencies, and, since these represent the higher audio frequencies, the high frequencies are missing in the output. The use of fidelity controls allows the selective circuits to be broadened for receiving high-fidelity local programs where there is not likely to be adjacent station interference. Yet it allows the circuits to be returned to the selective condition for tuning in weaker stations that cannot override interference.

FIDUCIAL INFERENCE. A type of statistical inference introduced by Sir Ronald Fisher. It is accepted as valid by some authorities but rejected by rather more. The basic idea may be illustrated as follows: let $f(x, \theta)$ be a frequency distribution of a statistic x, dependent on a parameter θ. In probabilistic terms, this would be thought of as a distribution of x which was determined when θ was fixed, x varying from sample to sample. Fiducial theory regards it as giving, for fixed x, a set of admissible values of θ, usually a range within which the true value may be supposed to lie.

FIDUCIAL MARK. An internally generated identification mark on a film; two or more of these are generally used for orienting a film for reading, and for determining the geometric center of the film. The L-shaped corner marks and the + mark near the picture center, which are on the focal plane of the Tiros vidicon camera are fiducial marks. Their appearance on the image permits various calibrations such as determination of the degree of enlargement needed to fit the picture to the rectification grids, etc.

FIDUCIAL POINT. 1. A point (or line) on a scale used for reference or comparison purposes.

In the calibration of meteorological thermometers, for example, the fiducial points are 100 °C (212 °F) and 0 °C (32 °F), which correspond to the boiling point and ice point of water at standard pressure (760 mm of mercury).

2. A reference point of known location on a map, graph, or image used to set the position for overlays of similar maps, graphs, or images.

AMS

FIELD. The term generally connotes associated and surrounding phenomena and finds numerous uses in science. 1. In mathematics, a set of elements (see later separate entry). 2. A field of force. 3. A radiation field. 4. A sound field. 5. A field of view. 6. In electric motors and generators, the field is the part of the machine that furnishes the magnetic flux that reacts with the armature to produce the desired machine action. The field may be the fixed part of the machine or, as is usually the case in synchronous motors and generators, the rotating part of the machine. 7. The electromagnetic energy radiated from an antenna system of a radio transmitter. 8. In a cathode-ray tube, one set of scanning lines making up a part of the final picture. 9. An electric field. 10. A magnetic field. 11. A gravitational field. 12. An assigned area in a computer record to be marked with information.

FIELD-EFFECT TRANSISTOR SWITCH (FET). An FET switch generally is a switch for controlling analog signals and is comprised of one or more field-effect transistors. In analog-switching and multiplexing applications the metal-oxide-semiconductor FET (MOS FET) is used. The absence of an offset voltage makes the FET suitable for switching low-level signals. Further, the high input impedance provides excellent isolation between signal path and drive voltage.

The FET can be used for switching at very high rates even though it is not as fast as bipolar switches. A relatively high "on" resistance is the main disadvantage of the FET. "On" resistance ranges from 50 to 200Ω. However, some devices are obtainable with less than 5OΩ "on" resistance.

There is no inherent offset voltage because there is no *pn*-junction in the signal path as there is, for example, in the bipolar transistor. The FET is a majority carrier device in which the conductance of a conducting channel between two electrodes, the source and the drain, is controlled by a signal applied to a third electrode, the gate. A field established between the channel and the gate, which is insulated from the channel by a thin layer of material (usually silicon dioxide), controls the width of the conducting channel, hence resistance, in the MOS FET. Thus, there is no *pn* junction in the signal path from source to drain. Consequently, there is no offset voltage as in the case of a bipolar transistor.

The FET is a voltage-controlled device — hence has a very high input impedance. The input impedance in the MOS FET is the capacitor formed by the gate and channel, separated by the insulating layer. Thus, the input impedance is very high, usually in excess of $10^9\Omega$. Leakage currents are very low. These are determined in the MOS FET by the dielectric properties of the insulating layer. The high input impedance and low leakage thus provide excellent isolation between drive signal and the signal being switched.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

FIELD EMISSION DISPLAYS. Field emission displays (FEDs) are flat, thin vacuum tubes that use arrays of electron emitters (cathodes) to produce electrons, which are accelerated toward a phosphor-coated (anode) faceplate that emits visible light. Although the general principle is the same as for a cathode ray tube (CRT), the electron emission is unlike that generated by a conventional CRT. Rather, the electron emission is developed from a cold (room-temperature) cathode. Also a CRT uses one high-voltage cathode for each of the three primary colors; the electron beam produced by that source is focused by a gun and scanned by electromagnetic deflection coils. In the FED, there are numerous cathodes per pixel, and there is a direct relationship between the cathodes and the associated pixel.

The typical FED under development relies on solid state, monolithic construction rather than on mechanically formed metal elements, although metal shadow masks are also used. This structure is enabled because the heated filament cathode is eliminated. The microscopic scale of the active matrix elements allows the devices to be made with photolithographic tooling. All of the addressing and writing hardware can be contained in or on the substrate.

There are several issues to consider when predicting the success of the FED. On the positive side is the promise of performance similar to a CRT, such as wide viewing angles and high luminance. Also, the production of an FED requires fewer resources than that of a full-color active matrix liquid crystal display (LCD) (for example, organic chemistry, numerous thin films, polarizers, filters, glass, and fluorescent tubes).

On the negative side is the difficulty of moving a vacuum electron device into largescale production. Today's CRT plants, for example, are huge facilities with enormously complex, highly automated, custom-made equipment. The FED must use some of this equipment along with equipment used to make active matrix LCDs. Cooperation and joint development is required for FED technology to become commercially successful.

The equipment and techniques needed for FED fabrication have advanced considerably since field emitter array development began more than 20 years ago. As other types of flat panels increase in size, FED technology will continue to benefit from equipment advances, particularly deposition equipment. Less effort and fewer resources have been spent on FEDs than on LCDs, yet some visually attractive matrix working prototypes have been demonstrated.

The technology originated at SRI International (http://www.sri.com/) under the team of Charles "Capp" Spindt and associates in the early 1970s. The initial efforts used an ultrahigh vacuum at approximately 10^{-9} torr. Eventually it was proven that the devices would work at the more reasonable levels consistent with conventional CRTs (10^{-6} torr). The work at SRI focused on high-density field emitter arrays, now known as Spindt cathodes or tips. The emitter is a microscopic cone of a refractory metal situated in a well made of an insulating material. See Fig. 1.

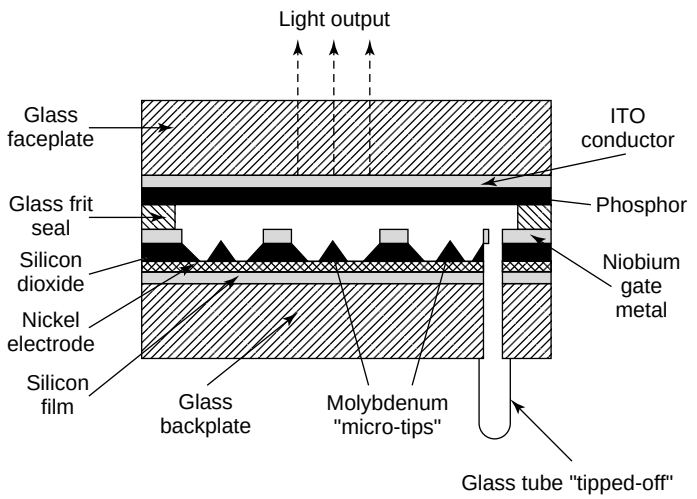

Fig. 1. Cross section of a field emission display.

A conductive grid layer is built near the height of the tip, which serves as the gate controlling the cathode emission. Tips are connected electrically as cathodes. An anode is situated from 0.1 to 1 mm away from the cathode. The cell is then evacuated. When a field of approximately 60 to several hundred volts is applied between the anode and the cathode, electrons are extracted from the tip. These electrons are then used to excite a phosphor into giving off visible light. A grid voltage of 20 to 60 volts is used to control the flow of electrons, turning a particular set of tips on or off. Other uses are for high-power microwave tubes or for very fast switches. Because the electrons are traveling only a very short distance, switching frequencies in the terahertz range (trillions of cycles per second) may be possible.

The phenomenon is based on the extremely high field strength at the tip, which must have a radius of 500 Å or less. A field of approximately 5×10^7 volts/cm is developed at the tip. At this high field intensity, electrons exhibit tunneling, a phenomenon that allows them to pass through the surface barrier (without the boost from thermal energy found in hot cathode devices). Much of the research work has been aimed at understanding the emission phenomenon in detail, with an attempt to achieve stable, reproducible, and controllable emissions. Uncontrollable emissions of up to 10^6 amps/cm^2 have been found. A controllable emission is sustainable at 10^3 amps/cm^2. Currents in the microamp range are sufficient for display applications.

One problem plaguing this technology has been the stability of the device over time. It now appears that stable emissions can be obtained at voltage levels low enough to avoid cathode sputtering. Any changes in the geometry of the tip will change the characteristics of the emission. Also, the vacuum level must be maintained without external help, for a very long time. This means that the device must be thoroughly outgassed and fitted with an oxygen getter to remove any potentially damaging oxygen.

The stability of the phosphor has also been a concern, especially when the formulation varies from the highly stable zinc oxide (ZnO) type used in vacuum fluorescent displays (VFDs). Device lifetimes exceeding 10,000 hours have been demonstrated; reproducibility of such performance in production volumes will be another challenge.

To form a flat panel display, the field emitter array must be combined with a phosphor plate. One approach is to build the emitting array on a base substrate and to support an ITO/phosphor-coated faceplate by pillars located in a black matrix between dots. Each red, green, and blue phosphor dot is activated by an array of 100 or more tips formed at the intersection of a grid and a cathode line. The large number of tips provides redundancy and uniformity by smoothing out emission fluctuations. The tips are spaced about 10 microns apart. The faceplate must be placed relatively near the emitters in order to avoid crosstalk, which results in a washout of colors. An alternative is to place the phosphors on the gate or grid layer and view them directly, as is done in a typical VFD.

Phosphors can be activated by voltages as low as 25 volts, in the case of a blue-green phosphor used for some VFDs. But an efficient red and blue phosphor requires a higher voltage. The typical blue phosphor is about 8 to 10 times less efficient than the most common green. Much more effort will be needed to match color phosphors in the 200 to 500 volt range so they can be used together on a display. Most companies are now using high voltages. Standard, high-voltage P-22 phosphors in FED design is used. These are high-efficiency emitters, so the problem of finding a low-voltage efficient phosphor is avoided. The problem then becomes accelerating the electrons to a high voltage within the FED structure.

The present status of the driving scheme for a standard triode structure requires about 100 volts to be switched (± 50 volts). The goal is to reduce the total switching field to 50 volts or less, which will allow the use of the same general type of CMOS complementary metal oxide semiconductor drivers used for STN-LCDs. Such a development would be a tremendous bonus for a light-emitting display, and it appears to be an achievable goal.

Researchers around the world are undertaking various approaches to substrate fabrication. A typical process would be as follows. A resistive material is first deposited and is needed to limit the current. A conductive layer is deposited and then etched into lines corresponding to the pixel or subpixel lines. An insulating layer is then deposited over the entire substrate, followed by a conductive gate metal layer. Next, aperture holes are patterned and etched through the metal and insulator, down to the cathode lines.

Refractory metal cones are then formed by depositing through the apertures. The array would then be attached to the phosphor faceplate, evacuated, and sealed. Chip-on-glass or tape-automated bonding packaged drivers may then be attached to the base substrate. Packaging of the display can occur under normal conditions with a tube inserted for evacuation of all gases at the end of assembly, or the entire assembly can be carried out under vacuum conditions.

Another persistent problem is the divergence of the electron beams. If the beam diverges beyond the phosphor area, color purity, contrast, or even display resolution can suffer. Two approaches are possible: maintaining close cell spacing or building focusing grids. Spacers, typically ceramic spheres, rods, or strips, must hold the glass plates flat across the extent of the display, under pressures of one atmosphere, while remaining electrically and optically neutral.

A key design choice is the voltage potential between the anode faceplate and the cathode array. High voltages (in the low thousands of volts) allow the use of efficient and well-developed phosphors, but require more complex device manufacturing. Low voltages (in the low hundreds of volts) allow for simpler and smaller devices, but suffer from inefficient phosphors, especially those that emit in the red and blue wavelengths.

A related tradeoff is the question of switched anode or nonswitched anode. A switched anode uses patterned transparent conductors as the base for the phosphors, and all phosphors of the same color are electrically connected. This avoids the problem of washout as stray electrons hit the wrong phosphors. The component cost is decreased as additional drivers are needed only to switch the red, green, and blue anodes, and the resulting color purity is excellent. Nonswitched anodes are typically used for high-voltage operation. For a nonswitched anode, there are no patterned anodes, only patterned phosphors. This can lead to washed out color unless some focusing or other corrective measure is taken.

Most Spindt emitter tip designs use molybdenum as the emitter material deposited through an electron beam process. Other cone-type emitters have been developed, such as silicon-based emitters, which are fabricated through a chemical mechanical polishing process. Besides Spindt tips, work

on other electrode designs is underway. The Naval Research Laboratory in Washington, D.C. (http://www.nrl.navy.mil/) has proposed an edge emitter as an alternative to the tip emitter. An edge emitter can deliver a very high emission current and may limit the amount of dispersion of the beam.

A promising new development is the approach that uses ink jet or screen-printing techniques to fabricate the emitter plate. One example is the surface-emitting FED developed by Canon, called the surface conduction emitter (SCE), which uses a thin film of palladium oxide with a gap created across the middle of the film. When a potential is applied across the gap, electrons tunnel through the gap and are emitted at the edge; they can then be collected by a phosphor-coated anode. One of the attractions of this approach is that many of the structures can be created with ink jet printing techniques.

The original work on microtip FEDs was done at SRI International and continued in earnest at LETI, the research laboratory of the French atomic energy agency, and pioneer in both monochrome and color FEDs. Pix Tech is the only company shipping displays to customers.

The lag time between the development of the technology and the onset of manufacturing has been much longer than many expected. As a result, the FED industry has restructured, causing some developers to leave, as well as causing mergers and joint partnerships. For example, the work on FEDs at FED Corporation (http://www.emagincorp.com/prsmart.htm) has stopped, and the company has shifted its development to organic LEDs. Motorola (http://www.motorola.com/General/index.html) continues to have an FED development program, but its plans to build a manufacturing plant have been put on hold, so the future of its FED program is in question. Other developers are placing less emphasis on FEDs and shifting toward research on organic LED technology, which has significantly lower manufacturing costs.

Merged company can now offer a broader line of displays, from small microdisplays for corders to large-screen FEDs for PC monitors. PixTech recently demonstrated a 15-inch color prototype.

Candescent Technologies (http://www.candescent.com/) recently joined with Sony Corporation (http://www.sony.com/) to develop and manufacture 15-inch, full-color FEDs for PC monitors. A high-quality, full-color FEDs in 5-inch (diagonal) sizes has been demonstrated. This joint development program should provide the manufacturing technology to build the larger units.

Canon (http://www.canon.com/) and Toshiba (http://www.toshiba.com/) have agreed to codevelop FEDs for large-screen, flat panel televisions, which will compete against plasma panels. The FEDs will be based on Canon's SCE technology. The idea is that many of the structures can be created with ink jet printing techniques, which promises lower manufacturing costs on large substrates. Printable Field Emitters in the United Kingdom is developing a device that uses thick-film techniques to fabricate large-area emitter arrays.

A large team of researchers, including W.B. Choi, at Samsung's Advanced Institute of Technology in Suwon, Korea, fabricated a 9-inch Carbon-Nanotube Based Field-Emission Display. Hollow carbon nanotubes (CNTs) with extremely small diameters as well as good chemical and mechanical strength have the potential to be applied to field emitters for FEDs as well as backlights for LCDs and outdoor displays. A 4.5-inch fully sealed CNT field emission display operating at a low voltage was demonstrated in 1998. A 9-inch color CNT-FED with diode- and triode-type geometry was developed in 1999. The structure of the CNT-FED consists of two glass plates; stripes of CNTs are patterned on the cathode plate and phosphor-coated indium tin oxide (ITO) stripes are formed on the anode plate. The gate electrode for the triode-type is inserted between the two plates. The display prototype had 240×576 pixels, matrix-addressable in a diode mode. A very uniform and stable moving image over the entire 9-inch panel was said to be obtained at the operating field of 2 V/m^2. The moving images produced demonstrate the potential for large-area and full-color display applications with low-cost fabrication and low power consumption.

A reflective-type CNT-FED was reported by Feng-Yu Chuang, et al., from the Electronic Research & Service Organization (ERSO) and Industrial Technology Research Institute (ITRI), Taiwan. The 3.5-inch panel with 60×120 pixels was fabricated by thick-film processes. A seven-segment numerical indicator showing digital images was also demonstrated using an opposed diode structure for comparison. Compared to Spindt type emitters, which use semiconductor processing, the CNT emitters were fabricated by a thick-film screen printing process that is cheaper and can be used to produce large panels. The phosphor on glass was patterned to form subpixels of 330×400 microns, which give a pixel size of 1.1 mm $\times$ 0.5 mm. Except for the bottom plate, the 3.5-inch fully sealed panel consists of another ITO plate on the front separated by 1-mm glass bars. The display feasibility of this structure was demonstrated to give 150 nits of brightness at each pixel, achieved by applying 500 volts between cathode and anode on the same plate. The average emission current density was 20 microamps/cm^2 with a phosphor efficacy of about 5 lumens/watt. In this configuration, the negative bias applied to the ITO-plate was designed to confine the divergence of the electrons. Also the operating voltage of reflective-type CNT-FEDs can be controlled by the thickness of the dielectric layer and the screen-printing layout. There is no need to limit the size of the gap between two plates; this makes vacuum processing of large panels possible. Furthermore, the luminance efficacy improves due to the reflective chromium layer under the phosphors.

The fabrication processes and the display characteristics of a color field emission display (FED) with a screen diagonal of 20 inches was reported by T. Guo, et al., from Fuzhou University in the Peoples Republic of China The panel was fabricated using a combination of thin-film, screen-printing, and surface-activation techniques; it could display Chinese characters, English letters, and simple cartoon images at 50 Hz. The pixel size of the FED prototype was 0.15 mm $\times$ 0.5 mm for a color FED or 0.5 mm $\times$ 0.5 mm for a monochrome FED. The panel had 358×358 pixels and was 2.2 mm thick. Under about 300 volts anode bias, the maximum emission current of one subpixel was about 26 mA. The luminance of a monochrome FED made with conventional CRT phosphors was 300 cd/m^2. However, the luminance of the color panel was said to be "low."

In 1998, T. Komoda and his co-workers at the Advanced Technology Research Laboratory of Matsushita Electric Company developed a cold cathode for FEDs using porous polysilicon (PPS) and demonstrated that the mechanism of the electron emission is quasi-ballistic, which is completely different from that of conventional FED types. It was also demonstrated that electron emission from this cold cathode is efficient and fluctuation-free, leading to the possibility that this PPS-based cold cathode could overcome the various drawbacks of the Spindt-type cathode. The research team first demonstrated the possible application of this cold cathode to a display in 1999 and named it "BSD" for Ballistic electron Surface-emitting Display. Recently this team, along with N. Koshida of the Tokyo University of Agriculture and Technology, reported on the performance of a newly developed prototype multicolor display using the BSD concept.

The multicolor prototype BSD panel had 53×40 pixels and measured 2.6 inches in diagonal. The fabricated panel was driven by a line-by-line sequence operation. The anode was formed from P-22 phosphors with a metal back film, and 5,000 volts were applied to the anode. No focus electrode was necessary. The average brightness at full white condition was about 100 cd/m^2. The emission current reached 2 milliamps/cm^2 and the emission efficiency was about 1%, which translates into a luminous efficacy of 6.8 lumens per watt. It was assumed that electrons were emitted perpendicular to the cold cathode face, as the size of each image on the screen was almost identical to the cathode emitter size. The light emitting pattern was clearly divided into about 0.3 mm dot pitch without any focusing electrode at a 5 mm distance between the anode and the cathode. FIELD INTENSITY. The field strength of a magnetic and/or electric field at any point. In radio the field intensity at the receiving antenna determines the signal which will be induced in the antenna and hence is an important consideration in the design of the transmitter. By proper choice of the power and frequency of the transmitter and type of transmitting

antenna considerable control may be exercised over the field intensity at the receiving point.

FIELD (Mathematics). A set of elements for which addition and multiplication are defined (and lead to elements in the set) such that: both operations are commutative and associative, and multiplication is distributive over addition. Also there are two elements, conveniently called 0 and 1, such that $0 + a = 1a$ for all a in the set; finally, subtraction and division are always possible and unique (except that division by zero is not possible). That is, for every a there exists a unique x such that $a + x = 0$ and a unique y (unless $y = 0$) such that $ay = 1$. Well-known examples of fields are: the set of real numbers, of complex number, of rational numbers, of residue classes, modulo a prime, etc.

FIELD OF VIEW. Of an optical instrument, the field of view is the angle subtended at the eye by the largest object, the whole of which can just be seen. This angle in the case of a simple telescope consisting of two converging lenses, is $a_2/(f_1 + f_2)$, with reference to Fig. 1, where a_2 is the aperture of the eye lens and f_1 and f_2 are the focal lengths of the objective and eye lens, respectively. If f_1 is doubled, thereby doubling the magnifying power, the field of view is nearly halved (f_2 is small compared with f_1). The falling off in brightness of the edge of the image, owing to some rays from the objective failing to strike the eye lens, is called vignetting. It is avoided or kept to a reasonable value by placing a circular opening, called the field stop, of suitable size where the image formed by the objective is situated.

FIELD STOP. An opening, usually circular, in an opaque screen which determines the field of view of an optical instrument.

FIELD STRENGTH. The strength of a field is its magnitude. Thus an electric field has a strength (volts per meter) at a given point, as well as a direction; its strength is, therefore, the magnitude of its electric field vector, **E**.

FIELD THEORY. The description of the physical world has evolved profoundly through the ages, at times because of, at other times being the cause of, sweeping changes in our philosophical, mathematical, and experimental knowledge. Greek geometry concerned itself essentially with properties of "objects as such," a triangle or a cube being studied, for example, without any thought of their spatial environment. The Ptolemaic system enhanced this view into a clockmaker's dream, where celestial bodies parade around the earth, rigidly driven in circular motions. Only with Descartes' analytical geometry did objects become "portions of space" and the properties of space itself the main object of study. With Galileo and Newton, a correct science of dynamics was born, which permits the prevision of an amazing number of mechanical phenomena in that space from a few first principles.

Field theory studies the phenomena of the physical world as due to interactions that propagate through space. The "geometrical emptiness," which is the space of mathematics, becomes the medium into and through which actions take place or, even more drastically, a structure which is itself determined by the properties of matter, as in general relativity.

Suppose two bodies interact in space, e.g., the sun and the earth with Newton's law, or two electric charges with Coulomb's law. Two pictures of this situation are equally possible and correct. One is that this interaction cannot be conceived if *both* bodies are not there and that we should study primarily its effects without looking for a detailed mechanism for its propagation from one body to the other. This is the description of

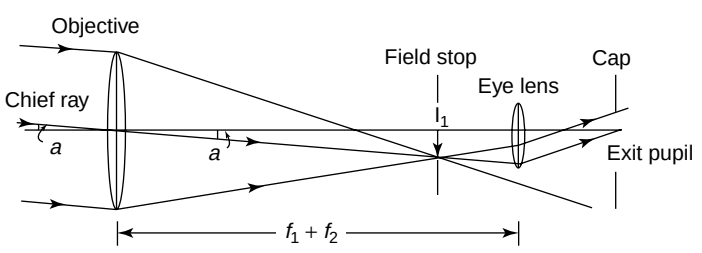

Fig. 1. Simple telescope, illustrating field of view.

"action at a distance," in which *forces* are the main concepts and space is a vacuum into which bodies follow trajectories determined by the forces acting upon them. The other picture consists in imagining that each body, whether alone or not, modifies the structure of the space which surrounds it. Space is modified either geometrically or because in each point of that space there is now potentially a force, which becomes active if another body occupies that point, but should be conceived as existing there in any case. The main objective here is to study both how these "fields of force" are created in space by material objects and how they propagate. This is the point of view of "action with contact," which finds its full development in field theory.

Mathematically, a field is characterized by assigning to each point of space a quantity *intrinsically* associated with it; a temperature, for instance, or a velocity, or a tensor or a spinor of arbitrary rank. "Intrinsic" means that, if we change our frame of observation, this quantity does *not* change; Suppose, e.g., that our field is that of the velocities at a given instant of all the points of a moving fluid. If we rotate our coordinate system we shall observe different values for the components of those velocities, just because we, not the velocities, have changed position. It is therefore essential that, together with the specification of the field quantities, their transformation laws also be assigned under changes of the reference frame. These laws are indicated by the description of the field quantity as a "scalar" (which does not change), a "vector" (which changes with the same law as the coordinates), a "tensor," etc. The complete specification of all such possible laws is a standard chapter of group theory.

Physically, we have to account for the creation or the existence of the field, by describing the field quantities as generated by "sources," such as positive or negative charges for the electromagnetic field, or the sources and sinks of hydrodynamics. Moreover, we have to describe in which way the values of the field quantities change when the point at which they are considered, or the time, is changed. In the absence of discontinuities, for instance in vacuum, one expects these values to differ by infinitesimal amounts, if the corresponding points are infinitesimally close, in some way typical of the field considered. In other words, one expects that the rates of change of the field quantities, with respect to the space coordinates and time, will be connected by relations that specify both how these changes can occur compatibly with the geometrical properties of space, and how they are related to the sources. Group theory determines all the possible forms that are permissible for these relations, which take the name of *field equations*; each field theory is characterized by a special set of field equations, which are clearly *partial differential equations.*

Relativity and quantum theory have played a great role in the development of field theory; we shall briefly discuss, later, their influence both in the explanation of new physical phenomena and in the mathematical formulation of the theory.

Field theory has taken an entirely new shape with the so-called second quantization, which has led to several modern developments. Some embody faithfully the concepts outlined thus far, and others instead represent new views in natural philosophy. This is still a matter of controversy at present, and it is unpredictable whether a reasonably lasting description of nature will come out of such attempts, or whether a new, drastic turn in human thought will be necessary before we can hope to understand the fundamental laws of physics. Be that as it may, the ideas and the computational techniques of field theory have proved already of invaluable help in the description of many phenomena, from particle physics to superconductivity.

It is convenient to examine first the theories in which the field quantities are ordinary functions of space and time points. This is regardless of whether they have a direct physical meaning (as with the velocities of hydrodynamics and the electromagnetic forces) or not (as with the wave function, which obeys a Schrödinger equation). This comprises of course most of classical and modern physics; mathematics permits again, however, a tremendous conceptual simplification. In the study of continuous media or fields one is, most often, interested in one of the following classes of phenomena:

1. Phenomena which consist of the propagation of some action; the medium itself is not transported from one place to another; typical is the propagation of waves, whether they be seismic, fluid or electromagnetic;

2. Phenomena in which there is transport or diffusion of a quantity in a medium: of heat in a wall, of solute, in a solvent, of neutrons in a pile;

3. Equilibrium phenomena: deformations of strained elastic bodies, electro- or magnetostatic fields as determined by charges and boundaries.

Each class is ruled by essentially one type of equation. Let $\Delta = \partial^2/\partial x^2/\partial y^2 + \partial^2/\partial z^2$ denote the Laplace operator; $\phi = \phi(x, y, z, t)$ the field quantity; F some function of x, y, z, t, ϕ and, at most, of the first-order derivatives of ϕ; v a velocity; and D a diffusion constant. The corresponding equations can be brought into the standard forms:

$$\Delta\phi - \frac{1}{v^2}\frac{\partial^2\phi}{\partial t^2} = F \text{ (hyperbolic partial differential)} \quad (1)$$

$$\Delta\phi - \frac{1}{D}\frac{\partial\phi}{\partial t} = F \text{ (parabolic partial differential)} \quad (2)$$

$$\Delta\phi = F \text{ (elliptic partial differential)} \quad (3)$$

If the field quantity has more than one component, one may deduce for each of its components an equation which is essentially of the same type, although it may be difficult or impossible to obtain an independent equation for each component.

This classification of physical phenomena according to the type of equation to which their study can be reduced is of the greatest importance. Equations (1), (2) and (3) are called in fact "the equations of mathematical physics"; more specifically, Equation (1) is also called the wave equation, Equation (2) the heat equation, and Equation (3) the Laplace or potential equation. The study of their mathematical properties gives complete information on all the physical phenomena they describe.

The equations of quantum mechanics can also be brought, at least formally, into the form of Equation (1) or (2); the intervention of complex quantities modifies the situation somewhat, in a way that we cannot discuss here.

Electromagnetic phenomena fall typically into the category of Equation (1): each of the components of the electric field $\mathbf{E} \equiv (E_x, E_y, E_z)$ and of the magnetic field $\mathbf{H} \equiv (H_x, H_y, H_z)$ satisfies, in vacuum, Equation (1), with $F = 0$; the connections between **E** and**H** are given by the Maxwell equations, which characterize completely the theory, and lead in vacuum to the result just mentioned. When **E** or **H** does not vary with time, Equation (1) reduces to Equation (3), thus yielding electro- or magnetostatics.

The electromagnetic field, i.e., the vectors **E** and **H**, generated by a distribution of moving charges or currents confined within a limited volume, has a part that becomes dominant at a large distance from that volume. This is because it decreases only with the inverse of that distance (instead of the inverse-square law of static fields). This part constitutes the *radiation* field, which is responsible for the transmission of energy and signals (the radiated energy is, of course, supplied by the mechanism that drives the generating charges or currents). This is easy to understand: the energy radiated through a large sphere around the source is proportional to the area of the sphere times the square of E. It vanishes therefore with increasing radius for all but the radiative component, for which it stays constant: energy is actually removed from the source and radiated away to all distances. The study of radiation is a most important part of the theory, both macroscopically (telecommunications, radar) and microscopically (atoms, nuclei, elementary particles).

Relativity and quantum mechanics have extended and modified profoundly the classical picture presented so far. The very concepts of space and time change with special relativity, because events that are simultaneous for an observer are not simultaneous when seen by another observer in uniform motion with respect to the first. This is because time and space are mixed together by the Lorentz transformations which relate the reference frames associated with the two observers. The laws of nature can retain their universal validity only if they are formulated in the same form by any such observer. That is, if their form is not altered by a Lorentz transformation — technically speaking, if they are "Lorentz covariant". This requirement becomes a stringent dogma; it suffices to determine, with the help of group theory, the possible equations for any conceivable relativistic field theory; it is of invaluable help, when computations are made, in checking or correcting them.

The nonrelativistic Schrödinger equation for the wave function of a particle is, but for the appearance of complex quantities, of the type (2) described before. This is not acceptable in a relativistic world, because time and space are not treated alike. One needs either an equation that contains only second-order derivatives, or one with only first-order derivatives. For a free particle, this leads either to the Klein-Gordon equation, which is of type (1), or it leads to the Dirac equation, which contains linearly only the first-order derivatives of the wave function. But the Dirac equation has a mathematical structure that necessarily assigns special physical properties to the particles described by it. It was one of the greatest triumphs theoretical physics ever witnessed, to discover that such properties are actually displayed by all particles that obey the Dirac equation: spin, and the existence for each Dirac particle of a corresponding *antiparticle*, i.e., a particle having the opposite mechanical and electrical properties.

The requirement of relativistic covariance has thus led to fundamental physical discoveries; for each particle obeying the Dirac equation, the corresponding antiparticle has been experimentally found in nature; electron and positron, proton and antiproton, neutron and antineutron, etc. What is more, the theory predicts that a particle-antiparticle pair can be created in a collision phenomenon, if sufficient energy is available, or can annihilate itself, giving away its energy in the form of electromagnetic radiation or other particles.

The classical theory allowed only for the electromagnetic radiation emitted by moving charges or currents; the creation or absorption of particles in collision phenomena, as well as the creation or annihilation of pairs, were outside its scope and possibilities. A new formulation of the theory was needed, which could account consistently for all such phenomena, handling situations in which particles can be created and destroyed in any numbers. The formalism devised for this purpose is that of quantum field theory.

The basic idea is to describe each type of particle by means of a field, which is no longer an ordinary numerical function of space and time. Rather, it is an "operator," i.e., a quantity that changes the number of particles existing in any given state of the system. If the field operator is known, one can then evaluate the probability of a given state (so many particles, with determined energies and momenta) changing into an equally determined, different state. If the particles do not interact among themselves or with other particles, no change is possible; if there is interaction, the field operator has a structure that can cause such transitions. The field equations appear to be essentially the same as those of the classical Maxwell, Klein-Gordon, Dirac theories, etc. Their structure is however fundamentally different, because they now must be equivalent to infinite sets of ordinary equations, which couple states with different and ever-increasing numbers of particles.

Fields that are associated with particles obeying Bose-Einstein statistics (of which any number can be found in any given state) have radically different mathematical properties from fields that are associated with particles obeying Fermi-Dirac statistics (of which at most one can be found in any given state). Examples of the first are photons (the massless neutral quanta of the electromagnetic field), pions (massive particles, with or without electric charge, which are believed to be responsible for nuclear forces), etc. Examples of the second are electrons and positrons, protons and antiprotons, etc.

The passage from numerical fields to operator fields is called "second quantization"; quantum field theory deals with operator fields.

Striking successes have been met with this approach. From a quantitative point of view, they are confined mostly to electrodynamics. There, very small deviations from the values predicted by the nonquantized theory, which were observed in the measurement of the magnetic moment of the electron and in the so-called Lamb shift, were accounted for with amazing accuracy by quantum field theory. Qualitatively, the new conceptual framework has proved extremely useful in understanding elementary phenomena, especially with the help of the diagrams devised by R.P. Feynman, which give a simple intuitive picture of collision and radiation processes involving elementary particles. Very little has been achieved quantitatively, though, for theories other than electrodynamics, because of the tremendous mathematical difficulties that arise as soon as the simplest approximation techniques are not applicable because the interaction is too strong. Nevertheless, these ideas have proved greatly helpful in many ways, in combination with general principles of symmetry, Lorentz invariance and causality.

A beautiful consequence of this conception, which assumes that particles are the quanta of a field (as photons were recognized by Einstein to be the quanta of the electromagnetic field) was the discovery of H. Yukawa. Yukawa found that whenever such quanta have a mass different from zero, the force they create between two bodies that interact by exchanging such quanta with each other must be an exponentially decreasing function of distance. This force can become of a Coulomb type only if the mass of the quanta vanishes. Thus, the Coulomb force can be explained as due to the exchange of photons among electric charges, the nuclear forces

(which have typically short ranges) as due to the exchange of massive particles among nucleons. Exchanges of this nature are not observable in the laboratory, because this runs against Heisenberg's indeterminancy principle; if enough energy is supplied, however, such quanta can actually break loose and do appear as the particles created in collision processes.

The mathematical difficulties encountered in quantum field theory are many, and there is as yet lack of agreement as to the best way to circumvent some of them. Besides mathematical complexity, which prevents all but the simplest calculations, there are many unsolved problems of mathematical rigor and apparent inconsistencies, which can be removed only by delicate analyses. Typical of the latter is the fact that unsophisticated calculations give infinite values for masses and charges of interacting particles, and a painstaking analysis is required to retrieve from them the significant physical values. This is the so-called renormalization procedure, which copes with infinities that are already, in part, present in the classical theory (such as the infinite electromagnetic contribution to the mass of a point-like charged particle, when computed from Maxwell's equations). This procedure also copes with infinities that in part originate from the new formalism (which permits, for instance, pair creation).

It is not yet certain whether such difficulties are due to the lack of adequate mathematical techniques or are the expression of a fundamental inadequacy of the theory to describe ultimate laws of nature. On the one hand, the attention of some theoreticians has been directed to perfecting the mathematical foundations of quantum field theory (giving rise to axiomatic field theory and to more rigorous methods of obtaining and studying the quantum field equations, etc.). On the other hand, most physicists have been trying new avenues, such as the S-matrix theory, dispersion relations, the so-called Regge poles, etc. These approaches have certainly led to very useful results, but they leave altogether at least as many doubts as hopes.

Whatever may be the future prospects of field theory as the correct means for describing the fundamental laws of nature, its tremendous usefulness in providing a conceptual framework, in inspiring new ideas, and in suggesting computational techniques has been overwhelmingly demonstrated in the last decades. It has now found a new, very fertile ground of application in the study of systems containing a very large number of particles, where it has already provided a reasonably good quantitative understanding of superconductivity and superfluidity, and promises many other results of interest in the study of solids and liquids.

FIESER, LOUIS F. (1899–1977). A distinguished American chemist, Fieser became professor of organic chemistry at Harvard in 1930 after teaching for several years at Bryn Mawr. He achieved the synthesis of vitamin K_1 and did fundamental research on cortisone, the chemistry of steroids, and aromatic carcinogens. His achievements as a chemist and educator are recognized throughout the world. Unique in his facility in laboratory demonstration and as a lecturer and author, he exemplified that rare combination of a great teacher and a profound scholar.

FIG TREE. See **Mulberry Family**.

FIGURE OF MERIT. 1. General term for various graphical relationships that summarize certain desirable features of amplifying devices. For example, the figure of merit for a magnetic amplifier has been defined as the ratio of power amplification of a given control winding to the response time of the magnetic amplifier, under specified control circuit conditions.

2. The current required to produce one device deflection (usually one millimeter on a scale at a distance of one meter) of a galvanometer.

3. Any quantity that expresses quantitatively the performance of a measuring device.

FILAMENT. The resistive element (1) in a common electric lamp and (2) in a thermionic tube through which current is passed to provide the temperature required for thermionic emission. The surface of the filament may supply the emission, or the filament may be employed as a heater for an indirectly heated cathode.

The term also is used in astronomy in connection with prominences. In the textile field, particularly in connection with synthetic fibers, individual strands of extruded nylon, rayon, and so on are often referred to as filaments. Often, many filaments are twisted together to form yarn.

FILARIASIS. Filariasis is caused by nematodes (roundworms) that inhabit the lymphatics and subcutaneous tissues. Eight main species infect humans. Three of these are responsible for most of the morbidity due to filariasis: *Wuchereria bancrofti* and *Brugia malayi* cause lymphatic filariasis, and *Onchocerca volvulus* causes onchocerciasis (river blindness). The other five species are *Loa loa*, *Mansonella perstans*, *M. streptocerca*, *M. ozzardi*, and *Brugia timori*. (The last species also causes lymphatic filariasis.)

The adult filariae sizes varying from 2 to 50 cm (3/4 to 19 inches) dwell in various human tissues where they can live for several years. The agents of lymphatic filariasis reside in lymphatic vessels and lymph nodes; *Onchocerca volvulus* in nodules in subcutaneous tissues; *Loa loa* also is found in subcutaneous tissues, where it migrates actively; *Mansonella streptocerca* lives in the dermis and subcutaneous tissue; and *Mansonella ozzardi* and *M. perstans* reside in body cavities and the surrounding tissues. The female worms produce microfilariae (200 to 300 μm; life span 3 to 36 months) which circulate in the blood, except for those of *Onchocerca volvulus* and *Mansonella streptocerca*, which are found in the skin. The microfilariae infect biting arthropods (mosquitoes for the agents of lymphatic filariasis; blackflies (*Simulium*) for *Onchocerca volvulus*; midges for *Mansonella perstans* and *M. streptocerca*; and both midges and blackflies for *Mansonella ozzardi*). Inside the arthropod, the microfilariae develop in 1 to 2 weeks into infective filariform (third stage) larvae. During a subsequent blood meal by the insect, the larvae infect the vertebrate host. They migrate to the appropriate site of the host's body, where they develop into adults, a slow process than can require up to a year.

Among the agents of lymphatic filariasis, *Wuchereria bancrofti* is encountered in tropical areas worldwide; *Brugia malayi* is limited to Asia; and *Brugia timori* is restricted to some islands of Indonesia. The agent of river blindness, *Onchocerca volvulus*, occurs mainly in Africa, with additional foci in Latin America and the Middle East. Among the other species, *Loa loa* and *Mansonella streptocerca* are found in Africa; *Mansonella perstans* occurs in both Africa and South America; and *Mansonella ozzardi* occurs only in the American continent.

Lymphatic filariasis is a parasitic disease caused by microscopic, threadlike worms. The adult worms only live in the human lymph system. The lymph system maintains your body's fluid balance and fights infections.

Lymphatic filariasis affects over 120 million people in 73 countries throughout the tropics and subtropics of Asia, Africa, the Western Pacific,

and parts of Central and South America. You cannot get the worms in the United States.

The disease spreads from person to person by mosquito bites. When a mosquito bites a person who has lymphatic filariasis, microscopic worms circulating in the person's blood enter and infect the mosquito. If the infected mosquito bites, one can get lymphatic filariasis. The microscopic worms pass from the mosquito through your skin, and travel to your lymph vessels. In the lymph vessels they grow into adults. An adult worm lives for about seven years. The adult worms mate and release millions of microscopic worms into the blood. Once you have the worms in the blood, if a mosquito bites, the infection to others can be given to others through mosquitoes.

Many mosquito bites over several months to years are needed to get lymphatic filariasis. People living or staying for a long time in tropical or subtropical areas where the disease is common are at the greatest risk for infection. Short-term tourists have a very low risk. An infection will show up on a blood test.

At first, most people do not know they have lymphatic filariasis. They usually do not feel any symptoms until after the adult worms die. The disease usually is not life threatening, but it can permanently damage the lymph system and kidneys. Since the lymph system does not work correctly, fluid collects and causes swelling in the arms, breasts legs, and, for men, the genital area. The name for this swelling is lymphedema (lim-FA-de-ma). The entire leg, arm, or genital area may swell to several times its normal size. Also, the swelling and the decreased function of the lymph system make it difficult for the body to fight germs and infections. More bacterial infections in your skin and lymph system will occur. This causes hardening and thickening of the skin, which is called elephantiasis (el-la-FAN-tie-ah-sis).

Lymphatic filariasis is a leading cause of permanent and long-term disability worldwide. People with the disease can suffer pain, disfigurement, and sexual disability. Communities frequently shun women and men disfigured by the disease. Many women with visible signs of the disease will never marry, or their spouses and families will reject them. Affected people frequently are unable to work because of their disability. This hurts their families and their communities. Poor sanitation and rapid growth in tropical and subtropical areas of the world, where the disease is common, has created more places for mosquitoes to breed and has led to more people becoming infected.

Prevention includes giving entire communities medicine that kills the microscopic worms and controlling mosquitoes. Avoiding mosquito bites is another form of prevention. The mosquitoes that carry the microscopic worms usually bite between the hours of dusk and dawn. For those who live in an area with lymphatic filariasis:

- Sleep under a mosquito net.
- Use mosquito repellent on exposed skin between dusk and dawn.
- Take a yearly dose of medicine that kills the worms circulating in the blood. The medicine will kill all of the microscopic worms in the blood and some of the adult worms. It does not kill all of them.

Definitive diagnosis of lymphatic filariasis requires the demonstration of microfilariae in the blood, although serologic tests for parasite somatic antigens may be useful. In endemic areas where *W. bancrofti* displays nocturnal periodicity, detection of microfilariae requires examination of blood obtained after midnight, or detection requires the examination of blood obtained during the daytime one hour after administration of a provocative dose of diethylcarbamazine (DEC), which is also the treatment drug of choice.

Onchocerciasis is an infection of humans by the filarial nematode *Onchocerca volvulus*, which is found in equatorial Africa and in elevated regions of Mexico and Guatemala. There are smaller foci of occurrence in other equatorial countries. Transmitted by black flies of the *Simulium* species, the disease occurs principally in areas lying within a few kilometers of rapidly flowing rivers and streams where the black flies breed. The life cycle of *Onchocerca volvulus* is similar to that of those nematodes that cause lymphatic filariasis. Adult worms reside, however, in subcutaneous tissue, often enclosed in fibrous nodules. Microfilariae, which in this instance lack an enveloping sheath, are released from female adults; they localize in skin and subcutaneous tissue and in the eye.

Clinically, the skin is most frequently involved and pruritis is common. Wrinkling, loss of elastic tissue, pigmental variations, papulovesicular lesions and localized areas of eczematoid dermatitis may develop with time. Firm, nontender nodules containing adult worms surrounded by fibrous tissues are often palpable in subcutaneous tissues. In Central America, nodules commonly occur on the head whereas in Africa they are more common over bony prominences. Ocular involvement is potentially serious and may cause blindness (sometimes referred to as "river blindness"). Conjunctivitis with photophobia is common. Punctate keratitis may develop within the cornea, but usually resolves without consequence. However, sclerosing keratitis and chorioretinal lesions may ensue and are the major cause of onchocercal blindness.

The principal method of diagnosis of onchocerciasis involves finding microfilariae in skin snips. A count of more than 100 microfilariae/mg of skin indicates a heavy infection. Use of the Mazzoti reaction can also lead to diagnosis of the infection: a 50 mg dose of DEC produces pruritis, rash, fever, and conjunctivitis.

Therapy for onchocerciasis is complicated by adverse reactions attendant upon chemotherapy. As indicated by the Mazzoti reaction, DEC, which does not kill adult worms, may initiate systemic reactions and may aggravate pruritis as well as exacerbate ocular symptoms. Premedication with corticosteroids, however, diminishes these effects. Suramin will kill adult worms, but has considerable toxicity. Mebendazole may offer better therapy in the near future, but ivermectin may become the medication of choice in as much as it appears to be better tolerated and to be more effective than DEC without causing corneal opacities.

E.A. Ottesen (Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland) and several research institutions (including the Madras Medical College and Government Hospital) have reported on a controlled trial of ivermectin and diethyl carbamazine in lymphatic filariasis. Invermectin is a semisynthetic macrolide antibiotic whose recent availability has transformed strategies for treating and controlling the filarial disease onchocerciassis, a major cause of blindness. Apparently, ivermectin destroys onchocerca microfilariae without triggering the violent side effects usually induced by the older antifilarial drug diethylcarbamazine. It is reported that a single oral dose of ivermectin may be effective over 6 to 12 months.

Loa loa occurs in the rain forests of Central and Western Africa and the disease loiasis is transmitted by horseflies and deer flies of *Chrysops* species. Adult worms reside in subcutaneous tissues and sheathed microfilariae circulate in the bloodstream with a diurnal periodicity, which maximizes their blood concentration at about noontime. Many patients have asymptomatic microfilaremia and the prominent clinical manifestations are related to migrations of adult worms. These produce "Calabar swellings," erythematous areas of subcutaneous tissue edema producing swellings up to ten centimeters in diameter. These swellings usually resolve in one to three days. Infection may also present dramatically when the worm migrates in the conjunctiva of the eye. Diagnosis is made by finding microfilariae in the blood although this is difficult even with concentration techniques. Eosinophilia may be marked and filarial antibody titers are usually elevated. Therapy consists of DEC three times daily for two to three weeks. Side effects are usually mild except with patients having very high numbers of circulating microfilariae; these may develop fatal encephalopathy.

FILAR MICROMETER. An instrument for measuring small distances in the field of an eyepiece. The filar micrometer consists fundamentally of two parallel wires, one being fixed, and the other capable of motion in the direction perpendicular to its length by means of an accurately cut screw. The pitch of the screw is carefully determined for various temperature conditions, and the head of the screw is graduated so that whole revolutions and fractions thereof may be read. See Fig. 1.

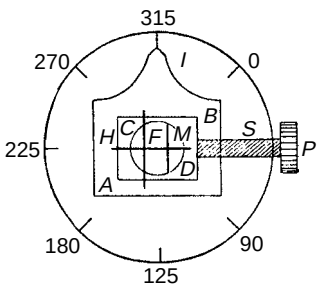

Fig. 1. Filar micrometer.

For astronomical purposes, the filar micrometer is somewhat modified. In the accompanying figure, AB is a plate of brass carrying two wires, H and F, which are accurately perpendicular to each other. This plate may be rotated, and the index I sweeps over a circle graduated in degrees, with a vernier reading fractions of a degree. A second plate CD may be moved over the surface of the first plate by means of the accurately calibrated screw S with the graduated head P. This plate carries on its lower surface, so that it will be practically in the same plane as F, a wire M, which is set accurately parallel to F.

This instrument is so mounted that F and M are in the focal plane of the objective of a telescope, with the optic axis of the instrument passing through the center of the opening in AB. When so mounted, the filar micrometer is one of the most valuable instruments for measurement of small angular distance.

The filar micrometer may also be used to determine the position of one astronomical body relative to another close object whose spherical coordinates are known. For this purpose, the wire H is first held at setting (R_1), (i.e., parallel to the celestial equator); the wire F is held on one of the two objects; and the wire M is set on the other. The distance thus measured is parallel to the equator (i.e., is proportional to difference in right ascension of the two objects). The instrument is then rotated through 90°, and the difference in declination may be measured.

FILE. A cutting tool for smoothing surfaces, breaking corners, removing burrs, and sharpening tools. The cut of a file denotes the degree of coarseness and the character of the teeth. Single-cut files have single rows of parallel teeth extending the length of the file; double-cut files have two parallel rows of teeth crossing each other; rasps have individual, or disconnected, teeth, as shown in Fig. 1.

A mill file is rectangular in section, and is single-cut and tapered in both width and thickness. A flat file is like a mill file, but is double-cut. A hand file is double-cut, of parallel width and tapered thickness, and has a safe edge (one which is smooth and has no teeth). Half-round files are usually double-cut, with one flat and one curved surface. Round files are of circular, tapered section, and may be single-or double-cut. Three-square and handsaw files are tapered and have a triangular cross

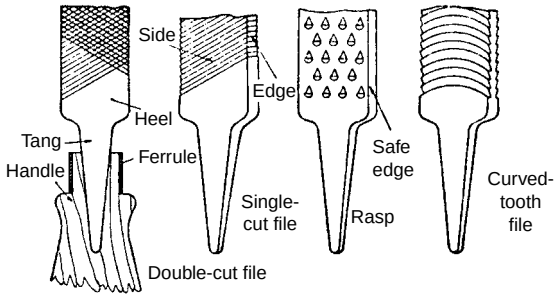

Fig. 1. Types of files.

section; they are used for filing to sharp corners, and for saw filing and sharpening.

FILE TRANSFER PROTOCOL (FTP). See **Transmission Control Protocol (TCP)/Internet Protocol (IP) Suite**; and **Wireless Communications Applications**.

FILE TYPES. Internet searching results in retrieval of information in the form of a file that can be displayed, downloaded, or executed. The organization of the file is called its format. The type of information as well as the way the information will be used determines the choice of file format. File formats and their file name extensions provide users with clues about what kinds of information the file contains — text, image, sound, video, animation, or data. To view, play back, manipulate, interpret, or alter the contents of a file requires different software tools or hardware configurations for different file types. This chapter examines a variety of file types: text, compressed, data, images, and multimedia formats. Possible uses and specific examples of each format are explored. Various file transfer tools and procedures are examined.

Text Files. There are four different text formats most commonly available on the Internet: plain text, rich text, hypertext, and word processor files [Hofstetter, 2005]. All browsers can display plain text, or ASCII, files. ASCII (American Standard Code for Information Interchange) is the most commonly used text format for Internet or computer files. Text files contain characters that can be viewed or printed, but they do not include formatting, such as special font faces, or styles, such as bold or italics. Files of this type usually have the file name extension .txt [Ackerman & Hartman, 2001].

Hypertext files contain text that has been surrounded with special HTML codes. The HTML coding defines how text will be displayed on the page (font face, font size, font color) as well as whether or not the text will appear in bold, italics, or underlined. HTML coding also permits text to function as a trigger or link that takes the user to another Web site, Web page, or place within the same Web page. Hypertext links can also launch various actions or activate multimedia files. Hypertext files have either .htm or .html file name extensions [Hofstetter, 2005]. The World Wide Web Consortium (W3C) maintains a Web site that provides information about HTML standards and specifications (http://www.w3.org/MarkUp/).

Such word processors as Microsoft Word and WordPerfect create files that contain proprietary formatting. The format codes within a word processor file determine font face, font size, margins, borders, headings, footers, and pagination [Hofstetter, 2005]. Word processing files have file names that may end in a variety of extensions, such as .doc (Word document file), .wpd (WordPerfect document file), or .rtf (rich text format). Unlike text and hypertext documents that can be opened and read by Web browser software, a browser cannot display word processor files. These files require helper applications in order to be opened and have their contents displayed. Rich text format files contain text that can be translated by multiple word processing programs.

PostScript is a file format invented by Adobe Systems. These files contain text, but they are usually not in a readable form. They contain commands that a printer or display device interprets — commands relating to formatting, fonts, font size, and images within the file [Ackerman & Hartman, 2001]. A PostScript file usually has a file name extension of .ps.

Although PostScript is recognized as the industry standard for printing and imaging, portable document format (PDF) files, also invented by Adobe, are more widely used for Internet document exchange

(http://www.whatis.com); [Miller, 1997]. Adobe Acrobat creates PDF files by converting word processor or printed documents into bitmap images. Although the software to create PDF files is not free, Adobe Acrobat Reader software, used to view PDF files, is available as a free download from the Adobe Web site, (http://www.adobe.com/products/acrobat/readstep2.html).

Text files in a variety of formats are used to provide online documentation, product order forms, registration forms, college catalogs, course handouts, newsletters, research articles, dissertations, publications, brochures, and more. If document layout and print formatting are unimportant, ASCII text files provide a simple method of sharing files on the Internet. Word processor text files are an appropriate choice for those working on collaborative projects, editing and augmenting each other's work. Hypertext files are well suited for online course content, interactive Web-based tutorials, online catalogs, forms, or lists of hypertext links. Portable document files duplicate desktop publishing formats, allowing users to view publications exactly as they were designed to appear in print versions. These files may be accessed by using a free downloadable reader and do not require any specialized application programs to open, print, or view.

Numerical Data Files. Spreadsheet programs, such as Microsoft Excel and Lotus 1–2–3, produce files containing data represented in a nontext format. Excel files have extensions of .xls. Lotus 1–2–3 files have extensions of either .wks or .wk1. As with word processor files; spreadsheet files need to be opened by the program used to create them. Newer versions of spreadsheet programs contain translation filters that can open and display data with any of the file extensions listed [Ackerman & Hartman, 2001]. In addition, Excel software allows files to be saved in HTML format, creating Web pages suitable for viewing on the World Wide Web. Data files are most often used to share or display statistical information, such as census data, mortgage rates, interest tables, and demographic breakdowns.

Compressed Files. Files are often compressed to save space on a server and to permit transfer that is more rapid over the Internet. One or more files can be packed into a single file. Once the user has downloaded a compressed file, the file will need to be unzipped or extracted to view, display, or use it. Users may download application software from the Internet to perform this function [Ackerman & Hartman, 2001].

Self-extracting archives are compressed files containing multiple application files or a set of data packed into a single file. After downloading a file to the computer's hard drive, the user must launch the archive file, which then unpacks the files and stores them on the computer. Many software companies now distribute application programs over the Internet using self-extracting archives [Hofstetter, 2001]. Examples of self-extracting software programs may be found at CNET's http://download.com.

A significant number of the files accessed through anonymous file transfer protocols (FTPs) are stored in a compressed format. The most common compressed or archived files are those with extensions of .zip, .gz, .hqx, .sit, or .tar. Shareware programs that work with compressed files are available from http://www.pkware.com; http://www.stuffit.com/expander/index.html; and http://www.winzip.com.

Image Files. Graphic image files may be stored in a variety of formats. Most Web browsers can display images stored in GIF (graphics interchange format) or JPEG (Joint Photographic Expert Group) format. Files with images in these formats have file name extensions of either .gif, .jpeg, or .jpg.

Tagged image file format (TIF or TIFF) is used to store and exchange high-quality bitmap images. Some browsers are unable to display TIFF files, necessitating the use of software applications that can either display or convert TIFF files to a format such as GIF or JPG, which can be viewed with any browser.

PNG (portable network graphics) is a new standard currently being developed by W3C. The new PNG format would provide a patent-free image file format that would replace GIF and TIFF format files.

BMP (Windows bitmap) images are composed of a grid broken into small squares called pixels. Each pixel contains color and location information. Because each BMP graphic contains a specific number of pixels, magnification can produce image distortion.

GIF. CompuServe Information Services introduced the GIF image format. GIFs were designed to be a platform-independent format designed for slow modem speed transfers (http://www.wdvl.com). GIFs are 8-bit compressed images that can be displayed without any loss of original graphic information. This process is known as lossless compression. GIF files are limited to a palette of 256 colors and are considered one of the standard image formats found on the Internet. A GIF file is encoded in binary as opposed to ASCII, or text, format. Binary files require the use of a software program to interpret their content. Transparent GIFs allow a background image color to be designated as "see through," allowing the illusion of images that float over a Web page's background color, texture, or graphics. Transparent GIFs may also be used to represent type fonts and blank spaces. GIF files can be in GIF 87a or GIF 89a format. The latter permits creation of an interleaved, or animated, image.

Animated GIFs. An animated GIF appears on a Web page as a moving image. Animated GIFS are created from a series of unique images saved within a single file in GIF 89a format. The animation displays a sequence of images that appear in a specific order. An animated GIF can display its sequenced images once and then stop, or it can loop endlessly.

JPEG. JPG, or JPEG, images are compressed 24-bit files that can contain over 16 million colors. JPGs are used to display digitized photographs, full color, and naturalistic gray-scale images. The JPG format allows a range of compression qualities. The greater the compression ratio the lower the display quality of the image and the smaller the file size. As with the GIF format, JPG is one of the standard Internet image formats.

PNG. Currently, the W3C is working on a new graphics format called PNG (portable network graphics). This format will handle images containing up to 48 bits of color information per pixel and will eventually replace the older GIF format. As with GIF, PNG image files are lossless, yet will permit compression rates 10%–30% more compressed than the GIF format.

An Internet committee designed the PNG format to provide a patent-free alternative to the GIF. Unlike the GIF format, PNG files not only support transparency, they also allow a range of transparency values. PNG also supports interlacing, gamma correction (the ability to tune the brightness of an image to correspond with specific monitor displays), and the ability to save in true-color, browser safe, or gray-scale formats (http://www.whatis.com).

Mapped Images. Mapped images contain an invisible layer of hyperlinks over the image. By moving the cursor over the image and clicking on various spots within the image, the user triggers the link [Weinman, 1999]. Links may retrieve external Web sites, Web pages, places within the same or another Web page, images, or other types of files, such as digitized videos or sound files.

Audio Files. In order to hear sound files from the Internet, the user needs to have a computer equipped with a sound card, speakers, or headphones, as well as a plug-in or helper application that works in conjunction with the Web browser software. When the Web browser encounters a sound file with a WAV, MIDI, NeXT/Sun, MP3, or audio interchange format, it downloads the entire file onto the hard drive of the computer. Depending on the file size and speed of the Internet connection, this may take several minutes. Once the download is completed, the helper application is launched. The Windows Media Player is an example of a helper application that might be used to play back audio files.

The Web browser then loads the sound file into the application. The application plays the sound. A plug-in performs the same function as a helper application only it does so inside the browser window rather than by starting up another software application [Burns, 1999].

Rather than downloading an entire audio file before activating playback, streaming audio downloads a portion of the sound file into a buffer, then continues downloading as playback proceeds. Information is transmitted from the Internet to the user's workstation in a steady, continuous stream. Because many users do not have high-speed Internet connections, streaming technologies are becoming an increasingly popular way to deliver online multimedia [Ackermann & Hartman, 2001; Hofstetter, 2005].

Sound files transmitted over the Internet often have one of the following formats:

- Waveform audio format (WAV), a standard format for computers using Microsoft Windows (file names end with .wav).
- NeXT/Sun format (file names end with .au or .snd).
- RealAudio format (file names end with .ra or .ram).
- Audio interchange format (file names end with .aif, .aiff, or .aifc).
- Musical instrument digital interface (file names end with .mid or .midi).
- MP3 format (a compression system for music files that does not diminish sound quality).

WAV. Microsoft created the WAV audio file format, which has become accepted as the standard PC audio file format. Both PC and Macintosh computers can use WAV files. The WAV file contains raw audio in an uncompressed format, as well as information about the file's number of tracks (mono or stereo), sample rate, and bit depth.

A waveform audio digitizer can be used to record sound. The waveform describes a unique sound's frequency, amplitude, and harmonic content. A waveform audio digitizer captures sound by sampling a waveform thousands of times per second, then storing the samples within a file format suitable for Internet transmission [Hofstetter, 2001].

AU/SND. NeXT and Sun computers produce sound files in a unique format. The audio file names usually end with the extensions .au or .snd. Audio files with extensions of .snd do not have file headers to indicate different sampling rates and compression formats, thus allowing variable recording and playback rates. Audio files with names ending in .au extensions are recorded and played back at a standard rate. Audio files produced by NeXT and Sun workstations provide a larger dynamic range than normal 8-bit samples, approximately equivalent to 12-bit samples [Hofstetter, 2005].

RA/RAM. RealAudio refers to continuous or streaming sound technology developed by Progressive Networks' RealAudio. RealAudio sound files are stored in a special format optimized for real-time transmission over the Internet and can be recognized by their file name extensions of either .ra or .ram. This is the format used for Internet radio broadcasts. Unlike other sound files, which must be completely downloaded before playback can occur, RealAudio files are downloaded and played simultaneously. RealAudio files must be played through a RealAudio player. The RealOnePlayer is able to read the file stream as it is coming in and begin playing it long before the rest of the file arrives, thus providing continuous, or streaming, audio [Hofstetter, 2005]. RealOnePlayer is available as a free download from http://www.real.com.

AIF/AIFF/AIFC. Audio interchange file format (AIF, AIFF, or AIFC) is the format used to create audio files on Macintosh computers. Sound files with the extension of .aifc indicate a Macintosh-produced audio that has been compressed. When used on a PC, these files usually have the file name extension .aif.

An AIFF file contains the raw audio data, channel information (monophonic or stereophonic), bit depth, and sample rate. AIFF files do not support data compression, so files in this format are usually large. Files with the extension .aifc indicate a compressed version of the AIFF format. The AIFC format supports compression ratios as high as 6:1.

MID/MIDI. The musical instrument digital interface (.mid or .midi) audio file format was designed to enable the recording and playing back of music on digital synthesizers supported by many makers of personal computer sound cards. Unlike other audio formats, MIDI does not directly record the actual sound. Instead, MIDI records information about how the audio file is produced. The information includes note-ons, note-offs, key velocity, pitch bend, and other methods of controlling a synthesizer.

The sound waves produced are those already stored in a wavetable in the receiving instrument or sound card. Codes within the MIDI file tell the sound card within the computer when to turn notes on and off, what volume to use, and what instrument should make the sound. MIDI files require little bandwidth to transmit, making them a popular format for transmitting audio over the Internet.

MP3. MPEG-1 audio layer-3 (MP3) compresses high-quality sound sequences into digital audio format. MP3 provides small file sizes (about one twelfth the size of the original file size) while retaining original sound quality. This results in compact audio files that download quickly without degradation of sound.

MP3 files require the use of a player, available for download from the Internet. There are multiple Web sites that provide access to MP3 music files, making them available for download. Two good sources for additional information about MP3 technology are http://MPEG.org and http://MP3.com.

Server-Side Files. The file types discussed earlier within this article reside on a Web server and are downloaded to the user's computer when accessed through the Internet. In contrast, server-side files not only reside on the Web server, they also perform some action while working from this location. Unlike other Internet file types, server-side files do not have to be downloaded to the computer user's hard drive to be used. Instead, they interact with user input, create a Web page on the fly, and then return a customized display.

Some types of server-side files interact with Web pages or a combination of Web pages, and database applications are stored on the Web server. Once connected to the Internet, the user accesses a Web page through the browser software application (Netscape, Microsoft Internet Explorer, or others). HTML coding within the Web page provides a path or map to the Web server directory where the server-side file is stored. This file is accessed and an action is performed. The action depends on the type of server-side file and the instructions it contains. It may generate a new HTML page, send information to or from an HTML form page, display an alert, take the user to a new URL (uniform resource locator, or Internet address), open a new browser window, or dictate the way Web page text is formatted and displayed.

Active Server Pages. An ASP makes use of scripting technology to create dynamic, interactive Web pages. The ASP contains HTML to define the Web page layout and embedded programming code written in a scripting language, such as visual basic script, Perlscript, or JS [Gladwin, 2001; Langley, 2001]. These scripts are processed on a Microsoft Web server. As a result of this action, a Web page is created on the fly based on the user's request and data accessed from a database. This page is displayed in the browser (http://www.whatis.com).

ASP allows developers to create Web pages that may be used to interact with databases or other applications. Online forms, Web pages that contain such dynamic information as news reports and stock market data, often make use of ASP. Once the browser requests a file from the Web server, an embedded script runs, pulling up a file with an .asp extension from the Web server. The requested information is returned to the browser in the form of a customized Web page.

Examples of some common server-side files include ASP or CGI, PHP, JS, and CSS.

Common Gateway Interface. CGI is a standardized procedure for transmitting information between a Web server and a script. The CGI script is usually written in a programming language, such as Perl. When a user types information into a Web page form, this input is transmitted to the Web server, where it is routed through the CGI to an application program that, in turn, processes the data. The program responds to the user's input by displaying an existing Web page in the browser, generating a custom Web page on the fly, or retrieving and displaying an image or multimedia file [Hayes, 1999; Castro, 2000].

Some examples of CGI scripts used in conjunction with Web pages to retrieve database information, then return this data within the format of a Web page created on the fly, include search engines or directories, online registration forms, online order forms, and electronic full-text databases (http://www.whatis.com).

PHP. Like ASP, PHP is a script language and interpreter used primarily on Linux Web servers. The PHP script is embedded within a Web page among the HTML codes. Before the page is sent to a user who has requested it, the Web server invokes PHP to interpret and then perform the actions called for in the PHP script. An HTML file that includes a PHP script usually possesses a file name extension of .php, .php3, or .phtml.

JavaScript. JS is a program that can be included in HTML coding on a Web page, or as a separate script file stored on a Web server and invoked by a line of code embedded as a part of the HTML coding. JS allows the creation of interactive Web pages, validation of online forms, dynamic HTML, and the creation of customized HTML pages on the fly [Negrino & Smith, 2001].

A server-side JS file is coded as a separate text file, saved with a file extension of .js, and stored on the Web server. A corresponding line of HTML code that tells the browser the URL of the .js file is embedded in the Web page's HTML coding. When that Web page is accessed, the JS file is retrieved from the server and runs inside the Web browser.

Cascading Style Sheets. Like JS, CSS coding can either be included in a Web page's HTML coding or saved as a separate text file that is stored on the Web server and invoked by a line of HTML code within a Web page. A server-side CSS is saved with a file name extension of .css. A style sheet allows Web page designers to specify the look and format of Web pages; set font face, style, size, and color; and define precise positioning of such elements as images or text, or both [Burns, 1999].

FILLER. 1. An inert mineral powder of rather high specific gravity (2.00-4.50) used in plastic products and rubber mix to provide a certain degree of stiffness and hardness and to decrease cost. Examples are calcium carbonate (whiting), barytes, blanc fixe, silicates, glass spheres and bubbles, slate flour, soft clays, etc. Fillers have neither reinforcing nor coloring properties, and the term should not be applied to materials that do, i.e., reinforcing agents or pigments. Fillers are similar to extenders and diluents in their cost-reducing function; exact lines of distinction between these terms are difficult, if not impossible, to draw. Use of fillers and extenders in plastics has increased in recent years due to shortages of basic material.

2. The cross or transverse thread in a fabric or other textile structure.

3. A metal or alloy used in brazing and soldering to effect union of the metals being joined.

See also **Diluent**; **Extender**; and **Reinforcing Agent**.

FILLET. Fillet is the term employed to describe a concave section of a body used to reinforce a reentrant angle formed by the intersection of two plane surfaces. It is purposely incorporated in patterns from which castings are to be made, since lines of stress radiating from sharp edges and corners are set up in the casting during cooling. These will be prevented, and the casting made measurably stronger, if the outside edges are rounded, and the inside filleted. Filleting is also employed to improve the appearance of a corner, or hide a crack, and for the purpose of replacing an angularity with a smoothly rounded surface. The junction of two parts, such as plates at right angles to each other, is often made with a weld of the fillet type, in which a small fillet of welding metal is laid down in the angle created by the intersection of the surfaces of the plates.

FILM (Boiling). See **Boiler (Steam Generator)**; and **Boiling**.

FILM BREAKER. See **Defoaming Agents**.

FILM (Bubble). See **Foam**.

FILM (Electronic). See **Microelectronics**; **Semiconductors**; and **Telephony (Telecommunications)**.

FILM (Photography). See **Photography and Imagery**.

FILM *(Structure)*. In its most general usage, film means any thin sheet of material used for covering, coating or wrapping, or any thin layer that enters into the structure, usually on or near the surface, of a substance or object. The term film also denotes the monomolecular layer that is formed on the surface of a solution or at an interface between two immiscible liquids. The adsorption is of such a nature that the free surface energy is a minimum. Insoluble and non-volatile substances placed on the surface of a liquid such as water may also under certain conditions spread out on the water surface to give a monomolecular film. Adsorbed films of gases or liquids are also formed on solids such as mica, sodium chloride, glass and metals. In some cases, such as the adsorption of vapors on solids at relatively high pressures, it seems that the films may be thicker than one molecular layer and may attain thickness of three or four molecules.

The term film is also applied to sheets of cellophane, polyethylene, polyvinylidene chloride, etc., used for wrapping and packaging of food products, meats, and poultry (especially shrink films that are stretched before application). These function as a moisture vapor barrier. Plastic films are also used as slip surfaces in concrete structures such as airstrips, ice rinks, and highways. Photographic film is made from cellulose acetate.

Types of Film

Condensed Film. A surface film in which the molecules are closely packed and steeply oriented to the surface. The molecular packing approaches that observed in the crystalline state.

Expanded Film. A state of film intermediate in area and other properties between gaseous and condensed films.

Gaseous Film. A film in which molecules move about independently on the surface and their lateral adhesion for each other is very small. At low surface pressures (π) and large area (A), a gaseous film obeys the relation $\pi A = kT$. At higher pressures an equation of the form $(\pi A - A_0) = xkT$ holds, where x is a constant.

Liquid-Expanded Film. This film occupies a much larger area than a condensed film, but is still a coherent film. It can form a separate phase from a gaseous film with which it is in equilibrium, and obeys the relation

$$(\pi - \pi_0)(A - A_0) = C$$

where π is the surface pressure, A the surface area, and A_0 the co-area of the molecule.

FILM (Thin). See **Thin Films**.

FILOVIRUSES. Filoviruses belong to a virus family called Filoviridae and can cause severe hemorrhagic fever in humans and nonhuman primates. So far only two members of this virus family have been identified: Marburg virus and Ebola virus. Four subtypes of Ebola virus have been identified: Ivory Coast, Sudan, Zaire, and Reston. The Reston subtype is the only known filovirus that does not cause severe disease in humans; however, it can be fatal in monkeys.

Structurally, *filovirus virions* (complete viral particles) may appear in several shapes, a biological feature called *pleomorphism*. These shapes include long, sometimes branched filaments, as well as shorter filaments shaped like a "6", a "U", or a circle. Viral filaments may measure up to 14,000 manometers in length, have a uniform diameter of 80 manometers, and are enveloped in a lipid (fatty) membrane. Each virion contains one molecule of single-stranded, negative-sense RNA. New viral particles are created by budding from the surface of their hosts' cells; however, filovirus replication strategies are not completely understood.

The first filovirus was recognized in 1967 when a number of laboratory workers in Germany and Yugoslavia, who were handling tissues from green monkeys, developed hemorrhagic fever. A total of 31 cases and seven deaths were associated with these outbreaks. The virus was named after Marburg, Germany, the site of one of the outbreaks.

After the initial outbreaks, the virus disappeared. It did not re-emerge until 1975, when a traveler, most likely exposed in Zimbabwe, became ill in Johannesburg, South Africa. The virus was transmitted there to his traveling companion and a nurse. A few sporadic cases of Marburg hemorrhagic fever have been identified since that time.

Ebola virus was first identified in 1976 when two outbreaks of Ebola hemorrhagic fever (Ebola HF) occurred in northern Zaire (now the Democratic Republic of Congo) and southern Sudan. The outbreaks involved what eventually proved to be two different subtypes of Ebola virus; both were named after the nations in which they were discovered. Both viruses showed themselves to be highly lethal, as 90% of the Zairian cases and 50% of the Sudanese cases resulted in death.

In 1989, a new Ebola virus subtype was identified in imported *cynomolgous macaques* (an Asiatic monkey, *Macacca fascicularis*) during an outbreak in a primate quarantine facility in the United States. This subtype causes severe illness in primates, but it did not appear to cause illness in the few humans infected. Another subtype, named Ivory Coast, was identified in a patient infected in that country in 1994. This incident provided the first evidence of Ebola virus infection in West Africa.

Between 1976 and 1995, Ebola virus appeared sporadically in Africa, with small to mid-size outbreaks confirmed between 1976 and 1979. In 1995, a large epidemic of Ebola HF occurred in Kikwit Zaire. Of the 316 people known to have contracted the disease, 80% died. Smaller outbreaks were identified in Gabon between 1994 and 1996.

It appears that filoviruses are zoonotic, that is, transmitted to humans from ongoing life cycles in animals other than humans. Despite numerous attempts to locate the natural reservoir or reservoirs of Ebola and Marburg viruses, their origins remain undetermined. However, because the virus can be replicated in some species of bats, some types of bats native to the areas where the virus is found may prove to be the viruses' carriers.

In an outbreak or isolated case among humans, just how the virus is transmitted from the natural reservoir to a human is unknown. Once a human is infected, however, person-to-person transmission is the means by which further infections occur. Specifically, transmission involves close personal contact between an infected individual or their body fluids, and another person. During recorded outbreaks of hemorrhagic fever caused by filovirus infection, persons who cared for (fed, washed, medicated) or worked very closely with infected individuals were especially at risk of becoming infected themselves. Nosocomial (hospital) transmission through contact with infected body fluids, via reuse of unsterilized syringes, needles, or other medical equipment contaminated with these fluids, has also been an important factor in the spread of disease. When close contact between uninfected and infected persons is minimized, the number of new filovirus infections in humans usually declines. Although in the laboratory the viruses display some capability of infection through small-particle aerosols, airborne spread among humans has not been clearly demonstrated.

During outbreaks, isolation of patients and use of protective clothing and disinfection procedures (together called viral hemorrhagic fever isolation precautions or barrier nursing) has been sufficient to interrupt further transmission of Marburg or Ebola viruses, and thus to control and end the outbreak. Because there is no known effective treatment for the hemorrhagic fevers caused by filoviruses, transmission prevention through application of VHF isolation precautions is currently the centerpiece of filovirus control.

In conjunction with the World Health Organization, the CDC has developed practical, hospital-based guidelines, titled *Infection Control for Viral Haemorrhagic Fevers in the African Health Care Settings*. The manual can help health-care facilities recognize cases and prevent further hospital-based disease transmission using locally available materials and few financial resources. See also **Ebola Hemorrhagic Fever**; **Marburg Hemorrhagic Fever**; and **Viral Hemorrhagic Fevers**.

FILTER (Communications System). A type of frequency discriminating network designed to select or pass certain bands of frequencies with low attenuation and cause very high attenuation to other frequencies. Filters may be classified according to their characteristics (e.g., low-pass, high-pass, band-pass, band-elimination) or according to their circuits (e.g., ladder, lattice, π and T). A *low-pass filter* passes all frequencies below a certain value, known as the cutoff frequency, with very little attenuation and then produces high attenuation for all above this value. A *high-pass filter* passes all above the cutoff frequency and a *bandpass filter* will pass a band or bands of frequencies and produce attenuation for all frequencies outside these pass regions. A *band-elimination filter* offers high attenuation to all frequencies in a certain band and low attenuation to all other frequencies.

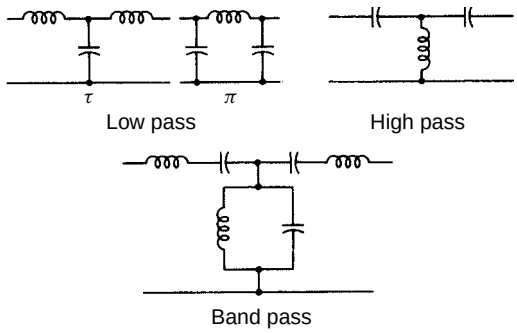

Fig. 1. Typical filter circuits.

Filters are made, normally, of combinations of series and shunt elements which are as pure reactance as can be economically attained, the purer the reactance the better the filter. Figure 1 shows the basic or prototype circuits for low-, high-, and bandpass ladder type filters. For more perfect action several sections may be connected in tandem, producing a ladder appearance. These sections may be connected as T or π circuits as shown. While these simple circuits are adequate for some purposes, most filters are composed of several sections, each introducing a specific characteristic. A discussion of the low-pass T connected filter will serve to illustrate the usual practice. The prototype shown in Fig. 1 will cause little attenuation up to the cutoff frequency but neither will it cause a high attenuation just above the cut-off, the attenuation increasing very gradually. To overcome this difficulty a section known as a derived section is connected in series with the prototype. This derived section, shown in Fig. 2, gives a very high attenuation at the resonant frequency of the shunt branch. If this resonant frequency is near the cutoff frequency the attenuation will rise rapidly at cutoff. Unfortunately, this section does not keep a high attenuation as the frequency is raised so it must be used with the prototype to give high attenuation at all frequencies above the cutoff. Often several derived sections, each having a different resonant frequency for its shunt branch, are used. The input and output impedance characteristics of these sections

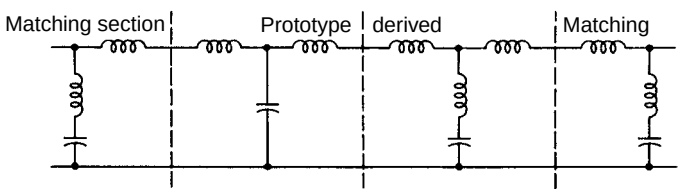

Fig. 2. Composite low-pass filter.

are not very satisfactory so a matching section is connected on each end to correct this. All of these various sections are designed to match one another and to have the same cut-off. The resulting filter, called a composite filter, will have a low attenuation pass band with no irregularities and then a high attenuation for all frequencies above this band. Other types of filters are built up in a similar manner. Quartz crystals are equivalent to resistance, capacitance and inductance networks having a very high **Q** so are ideal for filter components. Through the use of these crystals telephone carrier filters may be made to very close limits and thus many more carrier channels may be superimposed on the lines. These filters usually use a lattice type connection. See Fig. 3. A brief outline of the filter arrangement for a telephone line having a telegraph channel, a voice frequency channel and several carrier channels will serve to illustrate the use of the several filters discussed here. See Fig. 4. The telegraph signals are below the voice frequencies, and above the voice frequencies are several carrier channels. Each of these bands represents a separate communication that must be routed along the proper path at the terminals, all going over the same pair of line wires between stations. A high-pass filter connected across the line with its output going to the carrier equipment will allow the carrier frequencies to pass to this equipment and will block the voice and telegraph frequencies that are below its cutoff. A low-pass filter connected across the line at the same point will pass these lower frequencies and block the carrier frequencies. Then if the output of this low-pass filter feeds a high-pass filter with cutoff at the lower voice frequency the voice currents may be passed on to the phone circuits and the telegraph signals blocked. Similarly, a low-pass filter may be used to pass the telegraph and block the telephone currents. The carrier currents which were routed to the carrier circuits by the first high-pass filter are then routed to their respective channels for demodulating by band-pass filters, each designed to pass one channel.

The filters used in the power supplies of various electron tube circuits usually consist of series inductance and shunt capacity, and they are actually low-pass filters which cut out all the A.C. components of the rectified voltage and current. The bandpass filters used in intermediate frequency amplifiers are double-tuned, inductively coupled circuits which pass a band very narrow in proportion to the mid frequency.

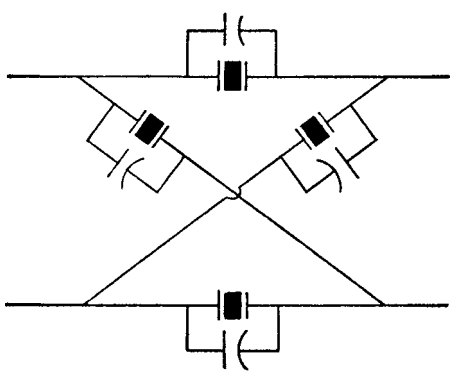

Fig. 3. Lattice-connected crystal filter indicating crystal elements.

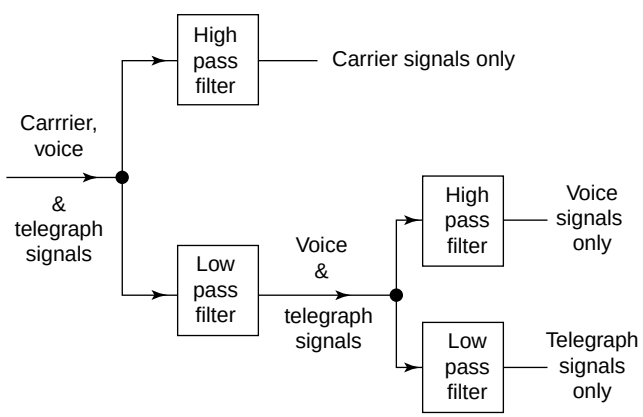

Fig. 4. Filter connection in multichannel telephone system.

Decoupling Filter. In most multistage amplifiers, there are certain circuits, such as voltage supplies, common to more than one stage. Since these common circuits provide a path through which energy may be fed from the output back into the input of some stages, serious feedback problems would result if something were not done to prevent them. The usual remedy is to insert a decoupling filter in those voltage supply leads that are common to more than one amplifier stage. These filters are frequently resistances in series with the lead and a by-pass capacitor from the device (tube or transistor) side of the resistor to ground. The resistance used must be low enough not to cause a serious loss of voltage and the capacitor should have a reactance which is low compared with the resistance at the lowest frequency for which the circuit is designed. Where the resistance would produce too much D.C. voltage drop or where it does not give enough filtering action, an inductance is sometimes used. For still more effective filtering a second resistance and condenser in cascade may be used.

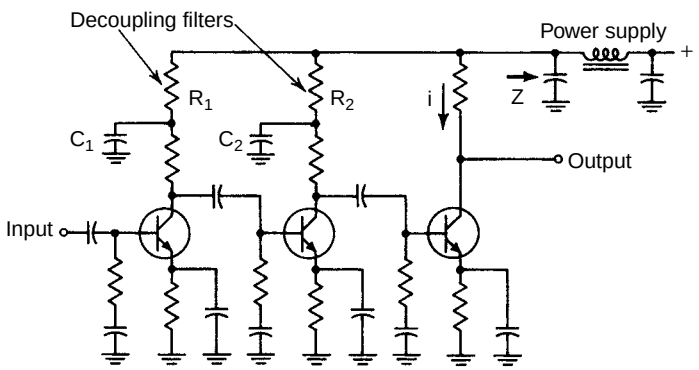

Fig. 5. Decoupling filters used in three-stage transistor amplifier.

Decoupling filters are used in the three-stage transistor amplifier shown in Fig. 5. The voltage developed across the impedance Z will cause additional components of signal current to flow in the base circuits of the second and third transistors. Use of the elements R_1, C_1 and R_2, C_2 causes a reduction of the signal fed back to an amount that does not deteriorate the amplifier performance unduly.

Paralleled-Resonator Filter. A bandpass filter in which output and input waveguides are coupled through several resonators. The resonators are resonant, coaxial lines with a center tuning-screw for alignment purposes. The coaxial resonators are coupled to the input and output guides by means of screws, which distort the field in the main guides. The phase of the coupling depends upon whether the screw is inserted into the bottom or the top of the waveguide. The coaxial resonators are placed a guide half-wavelength apart, so that they are effectively in parallel. The ends of the main guides are short-circuited a guide quarter-wavelength past the last resonator, so that the resonators are at a high-voltage position along the main guides.

Resistance-Capacitance Filter. A low-pass filter circuit sometimes used to lower the ripple content of a rectifier power supply. In its simplest form, it consists of a series resistor, followed by a shunt capacitor.

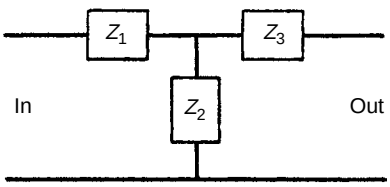

Fig. 6. T-section filter.

T-Section Filter. A wave filter, one section of which can be shown schematically as given in Fig. 6, if $Z_1 = Z_3$, the filter is said to be symmetrical.

PI-Section Filter. A wave filter, one section of which can be shown schematically as given in Fig. 7 (overleaf). If $Z_1 = Z_3$, the filter is said to be symmetrical.

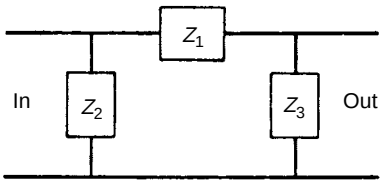

Fig. 7. Pi-section filter.

FILTER MEDIUM. Almost any water-insoluble, porous material having a reasonable degree of rigidity can serve as a filter. Sand is used in simple large-scale water filtration, the voids between the grains providing the porosity. In industrial operation, cotton duck, woven wire cloth, nylon cloth, and glass cloth are used. For laboratory work, Whatman filter paper, diatomaceous earth, and closely packed glass fibers are standard materials. Plastics membranes containing more than a million pores per square inch are used in bacteriological filtration.

See also **Filtration**.

FILTER WEDGE SPECTROMETER (FWS). See **Nimbus Satellite Program**.

FILTRATION. Filtration is the separation of two phases, particulate form, i.e., solid particles or liquid droplets, and continuous, i.e., liquid or gas, from a mixture by passing the mixture through a porous medium. In the simplest sense, filters separate a suspension into its component solid and liquid phases. The end result of the filtration may be one of several possible aims:

- Recovery of the liquid phase and discarding of the solid phase.
- Recovery of the solid phase and discarding of the liquid phase.
- Recovery of both the solids and liquid phases.
- Recovery of neither phase, as, eg, when water is cleaned prior to discharge to control water pollution.

The oldest recorded applications of filtration are the purifications of wine and water practiced by the ancient Greeks and Romans. Cake filters, such as the rotary vacuum filter and the filter press, were developed much later from the necessity to filter sewage.

Filtration is often referred to as mechanical separation because the separation is accomplished by physical means. This does not preclude chemical or thermal pretreatment used to enhance filtration. Although some slurries separate well without chemical conditioning, most pulps of a widely varying nature can benefit from pretreatment. See also **Flocculating Agents**.

In a filtration system the porous filtration medium is housed in a housing, with flow of liquid in and out. A driving force, usually in the form of a static pressure difference, must be applied to achieve flow through the filter medium. It is immaterial from the fundamental point of view how the pressure difference is generated but there are four main types of driving force, i.e., gravity, vacuum, pressure, and centrifugal. The two-types of filtration used most often in practice are cake, or surface, filtration and deep bed filtration. This division usually is unambiguous but in some cases, such as cartridge filters, there is no sharp dividing line.

Similarly to other unit operations in chemical engineering, filtration is never complete. Some solids may leave in the liquid stream, and some liquid will be entrained with the separated solids. As emphasis on the separation efficiency of solids or liquid varies with application, the two are usually measured separately. Separation of solids is measured by total or fractional recovery, i.e., how much of the incoming solids is collected by the filter. Separation of liquid usually is measured in how much of it has been left in the filtration cake for a surface filter, i.e., moisture content, or in the concentrated slurry for a filter-thickener, i.e., solids concentration.

Filtration-Related Processes

Several processes are used to enhance the filtration process itself. They may also be related processes in their own right. They include washing of solids, cake dewatering, pretreatment of suspensions (addition of inert filter aids), mechanical squeezing of cakes, electro-kinetic effects (Table 1), and magnetic separation.

TABLE 1. SUMMARY OF ELECTRO-KINETIC EFFECTS

Effect	Fluid	Particles	Electric field
electrophoresis	still	moving	applied
sedimentation (or migration) potential	still	moving	measured
electroosmosis	moving	still	applied
streaming potential	moving	still	measured
electroosmotic pressure	still	still	applied

Cake Filtration Theory

It does not matter, from the fundamental point of view, how the pressure drop is generated in the filter. In the case of the centrifugal filters there is an additional phenomenon of the mass forces acting on the liquid within the cake. The conventional filtration theory must be amended to include this effect.

Carman-Kozeny Equation. Flow through packed beds under laminar conditions can be described by the Carman-Kozeny equation in the form

$$\frac{Q}{A} = \frac{\Delta p}{\mu L}\frac{\varepsilon^3}{5(1-\varepsilon)^2 S_0^2} \tag{1}$$

where Q is volumetric flow rate, A is face area of the bed, L is depth of the bed, Δp is applied pressure drop, ε is voidage of the bed (porosity), S_0 is volume specific surface of the bed, and μ is liquid viscosity.

Darcy's Law and the Basic Filtration Equation. Darcy's law combines the constants in the last term of equation 1 into one factor K known as the permeability of the bed, i.e.,

$$K = \frac{\varepsilon 3}{5(1-\varepsilon)^2 S_0^2} \tag{2}$$

where K is a constant for incompressible solids. For compressible cakes, K depends on applied pressure, approach velocity, and concentration, and therefore presents serious problems in cake filtration testing and scale-up.

Modern filtration theory tends to prefer the Ruth form of Darcy's law, i.e.,

$$\frac{Q}{A} = \frac{\Delta p}{\mu R} \tag{3}$$

where R is the bed resistance. In cake filtration the bed resistance consists of the medium resistance in series with the resistance of the deposited cake, assuming no penetration of solids into the filtration medium; the general filtration equation is then written as

$$\frac{Q}{A} = \frac{\Delta p}{\mu R + \sigma \mu c V/A} \tag{4}$$

where σ is specific cake resistance, μ is liquid viscosity, c is solids concentration in the feed, V is filtrate volume collected since commencement of filtration, and R is medium resistance.

There is hidden assumption in equation 4 that the volume of the solids and liquid retained in the cake is negligible. This is reasonable at low concentrations but can lead to errors at high solids concentration and moisture contents of cakes. A corrected value of the concentration c can be used in equation 4 to reduce the errors, i.e.,

$$c(\text{corrected}) = \frac{1}{(1/c) - (1/\rho_s) - [(m-1)/\rho]} \tag{5}$$

where m is the mass ratio of wet to dry filter cake, ρ_s is solids density, and ρ is liquid density. This correction is necessary only at feed concentrations of greater than 200 g/L.

The scale-up of conventional cake filtration uses the basic filtration equation (eq. 4).

The feed solids concentration has a profound effect on the performance of any cake filtration equipment. It affects the capacity and the cake

resistance, as well as the penetration of the solids into the cloth which influences filtrate clarity and medium resistance. Thicker feeds lead to improved performance of most filters through higher capacity and lower cake resistance.

Prethickening of filter feeds can be done with a variety of equipment such as gravity thickeners, hydrocyclones, or sedimenting centrifuges. Even cake filters can be designed to limit or completely eliminate cake formation and therefore act as thickening filters and be used in this thickening duty.

High pressure drops have a twofold effect, i.e., on capacity and on displacement dewatering which often follows.

The most important feature of the pressure filters which use hydraulic pressure to drive the process is that they can generate a pressure drop across the medium of more than 1×10^5 Pa which is the theoretical limit of vacuum filters. While the use of a high pressure drop is often advantageous, leading to higher outputs, drier cakes, or greater clarity of the overflow, this is not necessarily the case. For compressible cakes, an increase in pressure drop leads to a decrease in permeability of the cake and hence to a lower filtration rate relative to a given pressure drop.

In batch filters, one of the important decisions is how much time is allocated to the different operations such as filtration, displacement dewatering, cake washing, and cake discharge, which may involve opening of the pressure vessel. All of this has to happen within a cycle time t_c which itself is not fixed, though some of the times involved may be defined, such as the cake discharge time.

If all of the nonfiltration operations are grouped together into a downtime, t_d, assumed to be fixed and known, an optimum filtration time t_{opt} in relation to t_d can be derived by optimizing the average dry cake production obtained from the cycle. For constant pressure filtration and where the medium resistance R and the specific cake resistance σ are constant, the following equation applies:

$$t_{\text{opt}} = t_d[1 + \sqrt{\frac{2\mu R}{\sigma c \Delta p t_d}}] \tag{6}$$

where Δp and c are the operating pressure drop and the feed solids concentration, respectively.

When the medium resistance R is small compared with the specific cake resistance σ, the second term in the above equation becomes negligible and the optimum filtration time t_{opt} becomes equal to downtime t_d. For any other case, t_{opt} is always greater than t_d. It follows, therefore, that the filtration time should be at least equal to the sum of the other nonfiltration periods involved in the cycle.

Vacuum Filters

In vacuum filters, the driving force for filtration results from the application of a suction on the filtrate side of the medium. Although the theoretical pressure drop available for vacuum filtration is 100 kPa, in practice it is often limited to 70 or 80 kPa.

In applications where the fraction of fine particles in the solids of the feed slurry is low, a simple and relatively cheap vacuum filter can yield cakes with moisture contents comparable to those discharged by pressure filters. Vacuum filters include the only truly continuous filters built in large sizes that can provide for washing, drying, and other process requirements.

Vacuum filters are available in a variety of types, and are usually classified as either batch operated or continuous. An important distinguishing feature is the position of the filtration area with respect to gravity, i.e., horizontal or nonhorizontal filtering surface.

Vacuum filters include the nutsche filter, enclosed agitated vacuum filters, the vacuum leaf filter, the tipping pan filter, horizontal rotating pan filters, horizontal belt vacuum filters, rotary vacuum drum filters, and rotary vacuum disk filters.

Batch Pressure Filters

Excluding variable chamber presses, which rely on mechanical squeezing of the cake and are discussed in a separate section, pressure filters may be grouped into two categories, i.e., plate-and-frame filter presses, and pressure vessels containing filter elements. The latter group also includes cartridge filters; these are discussed separately. All of the above pressure filters are suited to handling different types of cake. Pressure vessel filters (leaf-type) handle incompressible or slightly compressible cakes. Filter presses handle both compressible and incompressible cakes, especially with the flexibility potential of membranes. Variable chamber presses cannot be used on incompressible materials. Cylindrical element filters, i.e., candle filters, are used for clarification applications, using precoat and often body feed, resulting in cakes that are slightly compressible. Cartridge filters are for clarification only, with little if any cake formed.

Continuous Pressure Filters

A continuous pressure filter may be defined as a filter that operates at pressure drops greater than 100 kPa and does not require interruption of its operation to discharge the cake; the cake discharge itself, however, does not have to be continuous. There is little or no downtime involved, and the dry solids rates can sometimes be as high as 1750 kg/m^{2}h with continuous pressure filters.

Most continuous pressure filters available have their roots in vacuum filtration technology. A rotary drum or rotary disk vacuum filter can be adapted to pressure by enclosing it in a pressure cover; however, the disadvantages of this measure are evident. The enclosure is a pressure vessel which is heavy and expensive, the progress of filtration cannot be watched, and the removal of the cake from the vessel is difficult. Other complications of this method are caused by the necessity of arranging for two or more differential pressures between the inside and outside of the filter, which requires a trouble-some system of pressure regulating valves.

Despite the disadvantages, the advantages of high throughputs and low moisture contents in the filtration cakes have justified the vigorous development of continuous pressure filters.

Horizontal or vertical vessel filters, especially those with vertical rotating elements, have undergone rapid development with the aim of making truly continuous pressure filters, particularly but not exclusively for the filtration of fine coal. There are basically three categories of continuous pressure filters available, i.e., disk filters, drum filters, and belt filters including both hydraulic and compression varieties.

Disk filters include the McGaskell and Gaudfrin disk filters, the KDF filter, and the KHD pressure filter.

Drum filters include the TDF drum filter and the BHS-Fest filter.

Continuous compression filters include belt presses and screw presses.

The most important disadvantage of conventional cake filtration is the declining rate due to the increased pressure drop caused by the growth of the cake on the filter medium. A high flow rate of liquid through the medium can be maintained if little or no cake is allowed to form on the medium. This leads to thickening of the slurry on the upstream part of the medium; filters based on this principle are sometimes called filter thickeners.

The methods of limiting cake growth are classified into five groups, i.e., removal of cake by mass forces (gravity or centrifugal), or by electrophoretic forces tangential to or away from the filter medium; mechanical removal of the cake by brushes, liquid jets, or scrapers; dislodging of the cake by intermittent reverse flow; prevention of cake deposition by vibration; and cross-flow filtration by moving the slurry tangentially to the filter medium so that the cake is continuously sheared off. The extent of the commercial exploitation of these principles in the available equipment varies, but cross-flow filtration is exploited most often.

Centrifugal Filters

The driving force for filtration in centrifugal filters is centrifugal forces acting on the fluid. Such filters essentially consist of a rotating basket equipped with a filter medium. Similar to other filters, centrifugal filtration does not require a density difference between the solids and the suspending liquid. If such density difference exists sedimentation takes place in the liquid head above the cake. This may lead to particle size stratification in the cake, with coarser particles being closer to the filter medium and acting as a precoat for the fines to follow.

In centrifuges, in addition to the pressure due to the centrifugal head due to the layer of the liquid on top of the cake, the liquid flowing through the cake is also subjected to centrifugal forces that tend to pull it out of the cake. This makes filtering centrifuges excellent for dewatering applications. From the fundamental point of view, there are two important consequences of these additional dewatering forces. First, Darcy's law and all of the theory based on it is incomplete because it does not take into account the effect of mass forces. Second, pressures below atmospheric can occur in the cake in the same way as in gravity fed deep bed filters. The conventional filtration theory has been modified to make it applicable to centrifugal filters.

Due to good performance and high cost, centrifuges are often referred to as the Rolls-Royces of solid–liquid separation. They have parts rotating at high speeds and require high engineering standards of manufacture, high maintenance costs, and special foundations or suspensions to absorb vibrations. Another feature distinguishing the filtering centrifuges from other cake filters is that the particle size range they are applicable to is generally coarser, from 10 μm to 10 mm. In particular, cake filters that move the cake across the filter medium are restricted to using metal screens, which by their very nature are coarse. No cloth can withstand the abrasion due to the cake forced on the cloth and pushed over its surface. Only the fixed bed, batch-operated centrifuges can use cloth as the filtration medium and be used, therefore, with fine suspensions.

FINCH *(Aves, Passeriformes)*. Seed-eating birds of many species, found chiefly in the Northern hemisphere but to a limited extent in Africa and South America. They are small to moderately large and have a strong beak, usually conical and in some species very large.

In addition to the species whose names indicate their relation with the group, such as the greenfinches and the chaffinches, the finches include birds with distinctive names. The goldfinches, grosbeaks, cardinals, bramblings, siskins, linnets, redpolls, sparrows, canaries, and crossbills belong here. See also entry on **Passeriformes**.

Some species not described elsewhere in this volume include: The American goldfinches (*Astraggalinus tristis*), brightly yellow colored, with top of head, wings, and tail black, and with two white bands on the wings. The female is more drab, mostly olive. The male loses much of its coloration during wintertime. The goldfinch is about 5 inches (13 centimeters) long. A European species (*Carduelis carduelis*) is even more brilliantly colored, having a bright-red face. A goldfinch is sketched in the accompanying diagram.

The Siskin is a quietly colored finch, numerous species of which are found throughout the temperate part of the Northern hemisphere as well as South America. The pine siskin of North America, *Spinus pinus*, also called the pine finch, is finely streaked with brownish coloration on a lighter background: There are a few yellow marks on wings and tail.

The woodpecker finch (*Camarhynchus pallidus*) is the only bird known that uses a tool for obtaining food. The bird has been observed to visit holes made in trees by woodpeckers. By using a thorn picked up from the ground, the bird probes the holes, finding likely insects that stick to the thorn. This is a means of extending and making the beak of the bird more functional.

Recent studies by P.R. and R. Grant, P.T. Boag, and D. Schluter (University of Michigan) of Darwin's finches on the Galápagos Islands have revealed some interesting findings concerning the competition among species of finches. These findings may have broader implications concerning the abundance and distribution of organisms. For many years, competition between species (particularly closely related) was widely accepted as an important determining factor in the structuring of ecological communities. More recently, however, the competition paradigm has come under attack. By way of Galápagos Islands finches, Grant and his colleagues have been testing the competition hypothesis. In field work on the islands, the investigators concentrated on the distribution of two ground finches, *Geospiza difficilis* and *G. fuliginosa*. The researchers have tentatively concluded that the distribution of the birds on several separate islands supports the competition hypothesis. Other scientists are not convinced. This is a controversy that may continue among ecologists for quite some time.

FINENESS RATIO. 1. The ratio of the length of a body to its maximum diameter, or, sometimes, to some equivalent dimension — said especially of a body such as an airship hull or rocket.

2. A term analogous to the thickness ratio of an airfoil; often the inverse of that ratio. For example, the cross section of a streamlined strut or structural member may have a symmetrical airfoil shape whose fineness ratio would be defined by the ratio of the chord length to the maximum thickness, whereas the thickness ratio would be the inverse.

Airship shapes are characterized by fineness ratio, which usually varies from 5 to 8.

See also **Supersonic Aerodynamics**.

FINE STRUCTURE. In atomic spectra, the occurrence of a spectral line as a doublet, triplet, etc., due to the interaction or coupling between the orbital angular momentum and the spin angular momentum of the electrons in the emitting atoms. Fine structure is also exhibited by spectra of particles. See also **Atomic Spectra**.

FINGER LAKE. A glacial U-Valley or rock bowl which forms the basin for a fresh-water lake. Because of the character and origin of the basin, finger lakes are relatively long and narrow. Type locality, the Finger Lake region of New York State.

FINITE ELEMENT ANALYSIS. A powerful approximation technique used to solve problems in various engineering disciplines, such as the static and dynamic analysis of complex structures (aircraft, bridges, buildings, dams, machines, tanks, and ships), fluid flow and diffusion problems, and heat transfer and magnetic problems, among many others. Finite element analysis (FNA) rapidly gained acceptance with the availability of relatively high power digital computers during the 1970s and 1980s and, today, FNA can be considered a part of the overall structural and materials analysis techniques represented by the more generalized terms CAD (computer-aided design) and CAE (computer-assisted engineering). The term finite element method (FEM) is not the preferred term in contemporary literature.

One of the first mentions of finite element analysis was made by R.W. Clough at an American Society of Civil Engineers conference in 1960. A number of useful definitions for FEA have been offered:

1. A mathematical model of an object divided for structural analysis into an array of discrete elements (Hunt 1986); and
2. An interactive process in which suggested or required design changes are made known to the designer. Then redesigned product is again subject to analysis prior to going into production (Tver and Bolz 1984).

After creation of a geometric model, the engineer can calculate such factors as weight, volume, surface area, moment of inertia, center of gravity, among several other characteristics of a part. One of the most powerful methods for analyzing a structure is *finite element analysis*. Here, the structure is broken down into a network of simple elements and the computer uses them to determine stress, deflections, and other structural characteristics. The designer can "see" how a structure will behave before it is built and can modify it without building costly physical models and prototypes. The procedure can be expanded to a complete

system model, and operation of a product can be simulated. Finite element analysis can solve a complex problem by replacing it with many small but comparatively easy-to-solve problems. A complex geometry is replaced with a mosaic of small elements, called a *mesh*. Each element has a simple geometry, as shown in Fig. 1.

Mesh generation computer software may be used to quickly generate meshes for complex geometries. Advanced programs can automatically produce a mesh, given a part description. Some mesh generators use wire frame part definitions produced on a CAD (computer aided design) system as a starting point, while others use a solid model. Sometimes the user must manually subdivide the part into regions where the mesh generator merely interpolates within each region to form the elements.

Three basic rules apply to well-formed meshes:[1]

(1) Equally proportioned elements give best results. For example, the ratio between height and width of a quadrilateral element is called its *aspect ratio*. Generally, every element should have an aspect ratio of 3 to 1 or less. All types of elements give better results when they are so proportioned. See Fig. 2.

(2) Elements give better results when their interior angles correspond to a well-proportioned element. Figure 3 shows two different meshes that were used to model the same part. The quadrilaterals on the first model were skewed, while the second model maintained interior angles much closer to 90 degrees. When the part was analyzed with an FEA program, the first model did not converge to a solution, whereas the second one did. Figure 4 shows other examples of good versus poor interior angles.

(3) The size of the elements should vary according to the magnitude of the gradient of the output variable. In linear structural analysis, smaller elements should be used where stress concentrations occur. See Fig. 5. Such locations may be near notches and holes, necked-down areas, and boundaries between different materials. Node locations may also be adjusted for correct placement of loads and constraints. Nodes should be placed where concentrated loads occur, or where distributed loads change magnitude. Computer graphics can help the engineer inspect a mesh and determine if all of the elements follow the aforementioned suggestions. In some instances, it may be necessary to "slice through" a three-dimensional mesh in order to inspect interior elements.

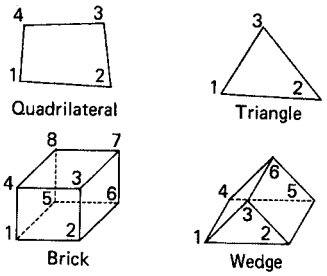

Fig. 1. Simple element geometries used in finite element modeling mesh.

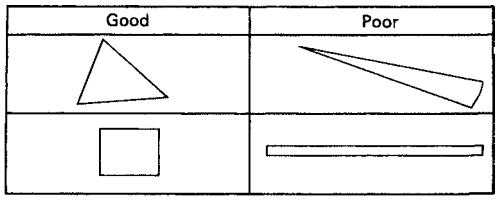

Fig. 2. Element aspect ratio.

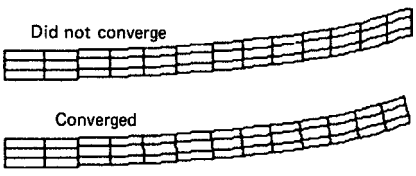

Fig. 3. Adverse effect of poor interior angles.

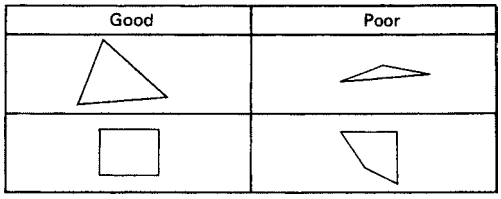

Fig. 4. Element interior angles.

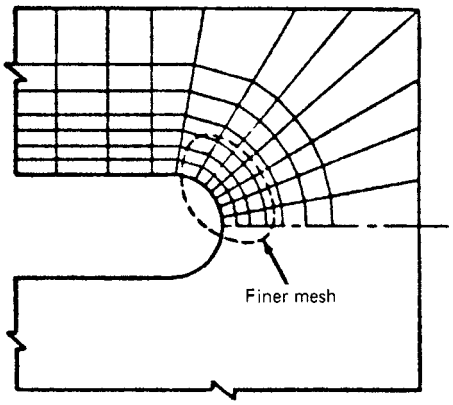

Fig. 5. Refining mesh at stress concentrations.

An example of the application of FEA to structural analysis is illustrated in Fig. 6. The subassembly analyzed for free-vibration is a Winchester disk drive recording head which comprises three parts: (1) a stainless steel sheet metal "suspension," which is spot-welded to (2) a "flexure," and (3) a ferrite "slider." The flexure produces a 10-gram pre-load on the slider so that it "flies" at the proper height (10 microinches) over the disk. The actual recording device is located on the slider. Positioning this head represents a problem in servocontrol of a flexible structure. The relatively complex geometry of this subsystem presents an interesting challenge in modeling. Three separate parts must be modeled: (1) the suspension, which necks down by factor of four from one end to the other; (2) the flexure, where two narrow strips require smaller elements than required in the remainder of the model; and (3) the slider.

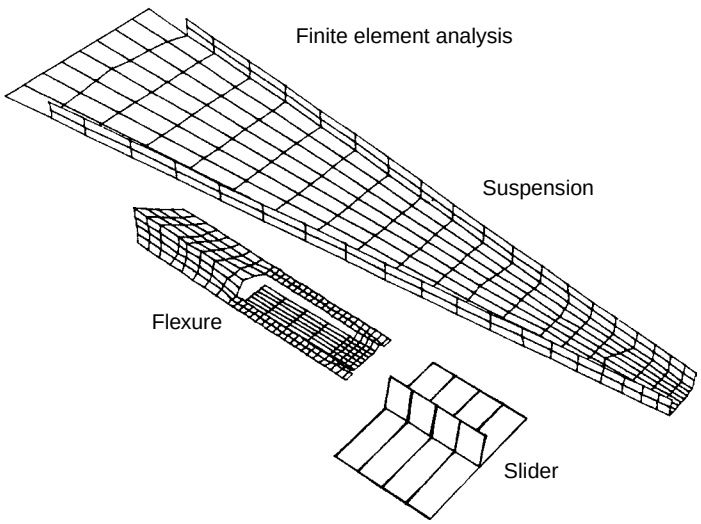

Fig. 6. Mesh of disk drive head assembly.

A wire frame model was generated, using *ComputerVision (CV) CADDS 4* software, after which the model was subdivided into flat regions. Variable node spacing was needed on the main part to reserve a good aspect ratio in

[1] Parts of this article were abstracted from "Finite Element Analysis" by B.A. Ross and T.N. Hurst in "Instrumentation and Computer Control in Applied Automation" (D.M. and G.D. Considine, Eds), Chapman and Hall, New York, 1988.

the elements as the part narrowed. The first and second parts are connected with four spot welds, which appear as irregularities in the suspension mesh. The spot welds were modeled by sharing nodes between two parts. It was necessary to move nodes on the parts in order to align them at the weld points. The final mesh consisted of 555 nodes and 456 elements. Once the mesh geometry was finalized, constraints, geometric properties, and materials properties were added. The problem was thus readied for further computer analysis.

As pointed out by Gruenberger (1983), many applied mathematicians view the finite element method as the approximation of a continuum by elements, each with multiple connecting points. It is similar to the Rayleigh-Ritz method, with the following differences: (1) the piecewise continuous field definitions used in the FEM are used to take care of irregular boundaries; and (2) the resultant equations from the FEM normally consist of banded or sparse matrices. Mathematicians point out that, while the finite difference method involves *mathematical lumping*, the FEM uses *physical lumping*. Moreover, the FEM, using a triangular element, is equivalent to the "hypercircle" method developed by R. Courant in 1943.

ANSYS Finite Element Analysis Program. Details of the currently popular ANSYS program for finite element analysis are given in the Selker reference listed. ANSYS databases allow the user to define, delete, and manipulate data. The two primary databases are (1) preprocessing database and (2) postprocessing database. The former organizes items such as model data and loadings, and the latter contains solution results. As the user enters data to define a model, they are automatically added to the preprocessing database. During the solution, the program automatically creates a postprocessing database of the results. Manipulation of the databases is by commands. When commands are issued to create a node, delete an element, or modify material properties, the preprocessing database is being altered. On-line graphics permit the analyst to verify a model and change it, if necessary. Specific capabilities include:

1. Boundary condition display on solid model or finite element model;
2. Input of data by graphic device (mouse, joystick, crosshairs);
3. Selection of existing data by graphic device;
4. General display manipulation (viewing direction, magnification);
5. Color;
6. Multiple display windows;
7. Hidden-line, section, and perspective displays;
8. Shaded images (hardware dependent);
9. Edge displays (removal of interior element outlines for clarity);
10. Shrink displays (separation of adjacent element lines from each other for clarity);
11. Distorted ratio displays (independent scaling in horizontal and vertical directions for better visualization); and
12. Overlaid displays (creation of composite displays).

FEA and Polymer-Matrix Composites. Polymer-matrix composites (PMCs) are displacing metal structures in aircraft and other structures where weight reduction, and assembly performance, are major targets. In PMCs, high-strength, high-modulus fibers are embedded in a lightweight polymer matrix. Designing and analyzing PMC structures is much more complex than simply designing metal structures. Fortunately, programs have been developed that permit FEA analysis of PMC structures with the same accuracy as with metal parts.

As mentioned by Putcha (Engineering Mechanics Research Corp., Troy, Michigan), general-purpose computer codes have been developed that are specially tailored for PMC analysis. The key element of such a program typically is the use of general isoparametric composite shell elements based on shear-deformation theory, which accounts for the effects of transverse-shear deformation, rotary inertia, material anisotropy, and all manner of bending/extension twist/shear couplings. Such elements are suited for the analysis of laminated anisotropic structures, as well as for the special situations of orthotropy, transverse isotropy, and isotropy. Usually, these composite elements are compatible with other elements, such as beam elements, so a structure may be part composite and part conventional material. Codes such as this, which are available from several major FEA software suppliers, have greatly simplified the analysis of composite structures.

FEA and Bulging Tank Analysis. Coke production in petroleum refineries involves both high temperatures and significant temperature cycling, conditions that can be conducive to mechanical failure in coking drums and horizontal coke coolers. Through the use of a finite element program, it is possible to determine if a horizontal coke cooler with large bulges could withstand operating loads as well as an earthquake.

A study of this problem, reported by DiRenz and Jones (Swanson Service Corp., Huntington Beach, California), reveals that the purpose of the FEA was not to determine the cause of the bulges, but rather to establish inspection and acceptance criteria for them. For this it was necessary to relate the bulge dimensions and location to vessel failure modes. The initial concern was failure due to elastic buckling. It should be mentioned that, because operating cycles repeat at approximately 24-hour intervals, the coke holding vessels develop, after weeks of use, "out-of-round" shape and bulges that can be seen easily with the naked eye. The end product of the FEA program was a graph and table that could be used by the inspection department for determining whether or not a given coke vessel should be reused. A typical stress pattern for a bulging vessel is shown in Fig. 7.

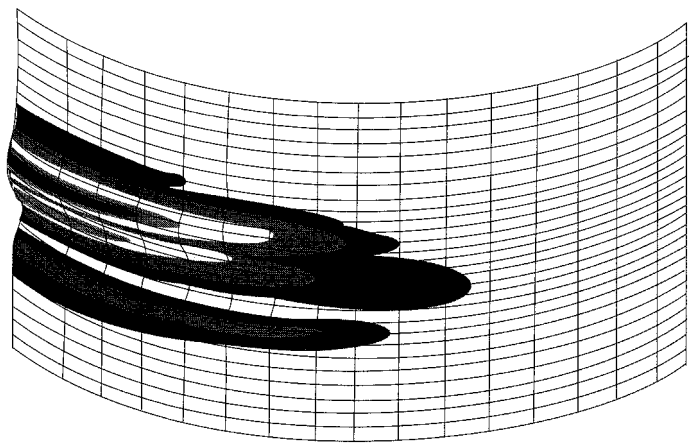

Fig. 7. Typical stress pattern produced for bulging coke drum. Finite element model shows the loading, symmetry boundary conditions, and antisymmetry boundary conditions. (*After DiRenz and Jones*.)

To convey the broad applications of FEA, it is interesting to note that in 1991 FEA was used (believed to be the first time) in the design of a stage set for Wagner's *Flying Dutchman*, presented at the Metropolitan Opera. Other unexpected uses include pediatric devices, such as knee braces for professional football players.

FINLAY, CARLOS JUAN (1833–1915). Finlay was a Cuban doctor, who implicated *Aedes aegypti* mosquitoes in the transmission of yellow fever. Finlay was born in Puerto Principe (now Camagüey) Cuba, the son of a Scottish physician, Edward Finlay, and a French mother, Isabel De Barrés. He was educated in Europe, and attended the Jefferson Medical College in Philadelphia. After graduation (1855), travel and a further study in Paris, Finlay returned to Havana, Cuba, married Adela Shine (1865) and established a medical practice. In the latter half of the nineteenth century, there was much confusion over the aetiology and transmission of yellow fever. Finlay speculated that female *Culex fasciatus* (now known as *Aedes aegypti*) mosquitoes spread some kind of living organism, arising from the miasma associated with rotting waste, from one person to the other.

Over a seventeen-year period (1881–1898), Finlay tried to refine his ideas about the transmission and immunity of yellow fever. He asked for volunteers among new arrivals to Cuba, allowing those who consented to be bitten by mosquitoes previously fed on yellow fever patients. He neither kept his volunteers in screened rooms (to prevent unintended infection), nor did he allow a sufficient time between bites for the causative organism (later shown to be a virus) to develop in the mosquito. His results were inconclusive and failed to impress his Cuban contemporaries. More generally interest focused on the putative *Bacillus icteroides*.

When the American Yellow Fever Commission, led by Water Reed arrived in Cuba in 1900, Finlay was keen to help. He provided the Americans with supplies of Aedes mosquitoes and their eggs, and shared his knowledge about rearing the insects. A skilled and experienced clinician, he also identified cases of yellow fever among those experimentally infected with the disease, clinical diagnosis being the only means available. Under rather more rigorous conditions than Finlay had employed, Reed *et al.* dismissed the competing ideas of infection by contact with fomites (dirty clothing and bedding belonging to yellow fever patients) and rejected the role of *B. icteroides*. They successfully determined that Aedes mosquitoes did transmit yellow fever from person to person but only after a period of time (*c.* 12 days), in which the mosquito served as a live incubator for the virus. By the time Reed's team arrived in Cuba, Ronald Ross' work on the mosquito transmission of malaria had established a new model for disease transmission, with the secondary host, the mosquito, serving an active developmental role for the parasite. See also **Reed, Walter (1851–1902)**.

Finlay deserves credit for championing his mosquito transmission theory amidst general skepticism and for specifying which mosquitoes were involved in the spread of yellow fever. However, his understanding of the role of a secondary host in disease transmission was poor and he did not pursue this line of research. He thought that the insect's proboscis acted like a needle, and that transmission was only a passive, mechanical process. He did not appreciate its role in incubating the causative organism. After the success of the American Yellow Fever Commission, however, the past ridicule in which his ideas had been held was quickly forgotten and he achieved iconic status in Cuba.

H. J.POWER, Wellcome Trust Centre for the History of Medicine at UCL, London, UK

FINSEN, NIELS RYBERG (1860–1904). Finsen studied medicine at the University of Copenhagen. After graduating in 1890 he became interested in the possible therapeutic uses of light. He demonstrated that the characteristic blistering of smallpox patients when exposed to the sun was due to blue, violet and ultraviolet rays in the light. He further showed that the red and ultra red rays at the opposite end of the spectrum promoted the healing of smallpox lesions.

In 1895 he turned his attention to another disfiguring skin disease, lupus vulgaris, a form of tuberculosis. He pioneered the use of concentrated light rays as a successful treatment for the disease. Following this success, with the financial help of two major benefactors, the first Light Institute was opened in Copenhagen in 1896. Finsen was appointed Director, and the Institute became a center of pilgrimage for many sufferers of lupus vulgaris. See also **Tuberculosis**.

Finsen placed the observations of earlier workers on a scientific footing and heralded a new era of phototherapy. For his work he was awarded the 1903 Nobel Prize for Medicine or Physiology. Due to poor health he was unable to collect his award in person, but he donated a portion of the prize money to the Light Institute. He died at the early age of 44, following a struggle against heart disease. He conducted experiments upon himself, keeping to a strict dietary regime, and his observations helped to lay the basis of the treatment of constrictive pericarditis.

CLAIRE E. J. HERRICK, London, UK

FIORD. A fiord is a glacially overdeepened valley, usually narrow and steep-sided, extending below sea level and occupied therefore by salt water. Typical fiords are to be found in Alaska and Norway; their depths, sometimes as much as 4000 feet (1219 meters), indicate that they are glaciated valleys which have been invaded by the sea after the disappearance of the glaciers. The word fiord is a variant of the Norwegian term for these features, *fiord*. The long fiord-like bays of the New England coast are sometimes referred to as fiards.

FIREBALL. A term used in astronomy to designate those meteors large enough to be apparently brighter than the planet Jupiter. They frequently leave a trail that may be visible for several minutes. Not infrequently a distinct sound is heard either during, or shortly after, the observation of a fireball. See also **Bolide**.

FIRE BRAT *(Insecta, Thysanura).* A wingless insect, *Thermobia domestica*, clothed with silky scales and bearing long antennae and three slender filaments at the opposite end of the body. Related to the silverfish but found in warm places; economic importance and control similar. The fire brat feeds on book binding, wallpaper paste, crackers, and other starch-containing substances. The insect is very active in its movements, is approximately one-half inch in length when mature, and prefers damp locations, such as basements.

FIRE-BRICK. Fire-brick is a type of brick capable of withstanding high temperatures and is used to line flues, stacks, furnaces, etc. Good resistance to heat flow is not to be secured simultaneously with refractoriness — indeed, the most refractory bricks generally have the highest thermal conductivities. Where necessary, insulation is added to minimize heat leaks. It is important for the refractory brick to be satisfactory on a number of points in addition to refractoriness, for resistance to melting is only one of several requirements to be met. Among these might be cited resistance to erosion by ash-laden gases, and to the fluxing action of molten slag. A good refractory should not spall badly under rapid temperature changes. The structural strength of fire-brick should hold up well as its temperature approaches the fusion temperature.

Modern installations often impose furnace conditions so severe that refractories other than fire-clay are needed. High aluminum and silicon carbide refractories are typical of these. The heat conductivities of the super-refractories are larger than those of fire-clay brick, and such construction should be backed up with high temperature insulation. Silicon carbide blocks are the most refractory and have the quality of resisting clinker adhesion better than ordinary fire-brick. Their fusion temperature is about 4000 °F (2204 °C).

Clay fuses at from 2800 to 3200 °F, (1538 to 1760 °C) the upper limit being for flint clay and the lower for the plastic form which, due to its cementing qualities, is especially valuable in fire-brick manufacture. Red brick is not suitable for refractory service, nor is insulating brick. There are several fire-clay furnace cements on the market that are adaptable to monolithic lining. The standard size of fire-brick and insulating brick is 9 inches by $4\frac{1}{2}$ inches by $2\frac{1}{2}$ inches (22.9 by 11.4 by 6.4 centimeters). See also **Refractories**.

FIRECLAY. This term is chiefly used by British geologists to designate the leached clays, rich in silica and alumina and low in alkalies and lime, which lie directly beneath coal beds. These clays are of economic

importance because they are refractory, and do not melt when heated to high temperatures.

FIREFLY *(Insecta, Coleoptera).* Harmless, soft-bodied beetles with a luminous organ in the abdomen. The flashing of these insects apparently enables them to find mates. The insects commonly are called lightning bugs. The wings are blue and lay flat to the body when at rest. The head is of orange coloration with two dark spots. The energy system for the lighting or flashing is of extremely high efficiency and involves enzyme reactions with oxygen. It has been found that the insect regulates the flashes of light by controlling the amount of air admitted to its bioluminescent organ. Details of the energy system will be found under **Bioluminescence**.

FIREMOUTH. See **Cichlids**.

FIRE-POINT. See **Petroleum**.

FIREWALL. Industrial or commercial buildings, standing adjacent, with common division wall, may be required to have special attention given to this wall, as to apertures, thickness and material, so as to prevent ignition or transmission of conflagration from one building to another. Such a wall would be a firewall.

FIREWALLS. When an organization or individual links to the Internet, a two-way access point out of and in to their information systems is created. To prevent unauthorized activities between the Internet and the private network, a specialized hardware, software, or software–hardware combination known as a firewall is often deployed.

Firewall software often runs on a dedicated server between the Internet and the protected network. Firmware-based firewalls and single-purpose dedicated firewall appliances are situated in a similar location on a network and provide similar functionality to the software-based firewall. All network traffic entering the firewall is examined, and possibly filtered, to ensure that only authorized activities take place. This process may be limited to verifying authorized access requested files or services, or it may delve more deeply into content, location, time, date, day of week, participants, or other criteria of interest. Firewalls usually provide a layer of isolation between the inside, sometimes referred to as the "clean" network, and the outside or "dirty" network. They are also used, although less frequently, to separate multiple sub-networks so as to control interactions between them.

A common underlying assumption in such a design scenario is that all of the threats come from the outside network or the Internet, but many modern firewalls provide protection against insiders acting inappropriately and against accidental harm that could result from internal configuration errors, viruses, or experimental implementations. Research consistently indicates that 70–80% of malicious activity originates from insiders who would normally have access to systems both inside and outside of the firewall. In addition, outside threats may be able to circumvent the firewall entirely if dial-up modem access remains uncontrolled or unmonitored, if radio-LANs (local area networks) or similar wireless technology is used, or if other methods can be used to co-opt an insider, to subvert the integrity of systems within the firewall, or to otherwise bypass the firewall as a route for communications. Incorrectly implemented firewalls can exacerbate this situation by creating new, and sometimes undetected, security holes or by creating such an impediment to legitimate uses that insiders subvert its mechanisms intentionally. It is often said that an incorrectly configured and maintained firewall is worse than no firewall at all because it gives a false sense of security.

Advantages. When properly configured and monitored, firewalls can be an effective way to protect network and information resources. Firewalls are often used to reduce the costs associated with protecting larger numbers of computers that are located inside it. Firewalls provide a control point that can be used for other protective purposes.

Disadvantages. Firewalls can be complex devices with complicated rule sets; 2) Firewalls must be configured, managed, and monitored by properly trained personnel; 3) A misconfigured firewall gives the illusion of security; 4) Even a properly configured firewall is not sufficient or complete as a perimeter security solution; 5) The processing of packets by a firewall inevitably introduces latency which, in some cases, can be significant; and 6) Firewalls often interfere with network applications that may expect direct connections to end user workstations such as Voice over Internet Protocol (IP) phones and VPNs (virtual private networks) as well as some collaborative tools such as instant messenger, and video and audio conferencing software.

Firewall Basics

A given firewall may, but does not necessarily, offer any or all of the following functions.

Address Filtering. This function can, and perhaps should, be performed by a device other than the firewall, such as a border router. Based on address filter tables, containing allowed or disallowed individual or groups (subnets) or addresses, address filtering blocks all traffic that contains either disallowed source or destination addresses. Address filtering by itself may not provide adequate protection because it is too large a granularity for some protective requirements.

Port Filtering. Port filtering goes beyond address filtering, examining to which function or program a given packet applies. For example, file transfer protocol (FTP) typically uses ports 20 and 21, inbound electronic mail (simple mail transfer protocol; SMTP) typically uses port 25, and inbound nonencrypted Web traffic (hypertext transfer protocol; HTTP) typically uses port 80. Attacks are often targeted and designed for specific ports. Port filtering can be used to ensure that all ports are disabled except those that must remain open and active to support programs and protocols required by the owners of the inside network. Static port filtering leaves authorized ports open to all traffic all the time, whereas dynamic port filtering opens and closes portions of protocols associated with authorized ports over time as required for the specifics of the protocols.

Domain Filtering. Domain filtering applies to outbound traffic headed through the firewall to the Internet. Domain filtering can block traffic with domains that are not authorized for communications or can be designed to permit exchanges only with authorized *outside* domains.

Network Address Translation. When organizations connect to the Internet, the addresses they send out must be globally unique. In most cases, an organization's Internet service provider specifies these globally unique addresses. Most organizations have relatively few globally unique public addresses compared with the actual number of network nodes on their entire network.

The Internet Assigned Numbers Authority has set aside the following private address ranges for use by private networks: 10.0.0.0 to 10.255.255.255 172.16.0.0 to 172.31.255.255 192.168.0.0 to 192.168.255.255

Traffic using any of these *private* addresses must remain on the organization's private network to interoperate properly with the rest of the Internet. Because anyone is wel come to use these address ranges, they are not globally unique and therefore cannot be used reliably over the Internet. Computers on a network using the private IP address space can still send and receive traffic to and from the Internet by using network address translation (NAT). An added benefit of NAT is that the organization's private network is not as readily visible from the Internet.

All of the workstations on a private network can share a single or small number of globally unique assigned public IP address(es) because NAT mechanism maintains a table that provides for translation between internal addresses and ports and external addresses and ports. These addresses and port numbers are generally configured so as to not to conflict with commonly assigned transmission control protocol (TCP) port numbers. The combination of the shared public IP address and a port number that is translated into internal address and port numbers via the translation table allows computers on the private network to communicate with the Internet through the firewall. NAT can also run on routers, dedicated servers, or other similar devices and *gateway* computers often provide a similar function.

Data Inspection. The primary role of many firewalls is to inspect the data passing through it using a set of rules that define what is and is not allowed through the firewall and then to act appropriately on packets that meet required criteria. The various types of firewalls, described below, differ primarily in what portions of the overall data packet are inspected, the types of inspections that can be done, and what sorts of actions are taken with respect to that data. Among the data elements that are commonly inspected are the following:

- IP address,
- TCP port number,
- User Datagram Protocol port number,

- Data field contents,
- Contents of specific protocol payloads, such as HTTP, to filter out certain classes of traffic (e.g., streaming video, voice, music, etc.), access requests to restricted Web sites, information with specific markings (e.g., proprietary information), content with certain words or page names.

Virus Scanning and Intrusion Detection. Some firewalls also offer functionality such as virus scanning and intrusion detection. Advantages of such firewalls include the following:

- *One-stop shopping* for a wide range of requirements,
- Reduced overhead from centralization of services, and
- Reduced training and maintenance.

Disadvantages include the following: Increased processing load requirements,

- Single point of failure for security devices,
- Increased device complexity, and
- Potential for reduced performance over custom sub solutions.

Firewall Types

Another difficulty with firewalls is that there are no standards for firewall functionality, architecture, or interoperability. As a result, users must often be aware of how firewalls work to use them, and owners must be aware of these issues to evaluate potential firewall technology purchases. Firewall functionality and architectures are explained in the next few sections.

Bastion Host. Many firewalls, whether software or hardware based, include a bastion host — a specially hardened server or a trusted system designed so that the functionality of the device cannot be compromised by attacking vulnerabilities in the underlying operating system or software over which its software runs. Specifically, the bastion host employs a secure version of the operating system with the most recent patches, security updates, and minimum number of applications to avoid known and unknown vulnerabilities.

Packet Filtering Firewalls. Every packet of data on the Internet can be identified by a source address normally associated with the computer that issued the message and the destination address normally associated with the computer to which the message is bound. These addresses are included in a portion of the packet called the header.

A packet filter can be used to examine the source and destination address of every packet. Network access devices known as routers are among the commonly used devices capable of filtering data packets. Filter tables are lists of addresses with data packets and embedded messages that are either allowed or prohibited from proceeding through the firewall. Filter tables may also limit the access of certain IP addresses to certain services and sub services. This is how anonymous FTP users are restricted to only certain information resources. It takes time for a firewall server to examine the addresses of each packet and compare those addresses to filter table entries. This filtering time introduces latency to the overall transmission time and may create a bottleneck to high volumes of traffic. A filtering program that only examines source and destination addresses and determines access based on the entries in a filter table is known as a port-level filter or network-level filter or packet filter. Hardware implementations of such filters are often used to provide low latency and high throughput.

Packet filter gateways can be implemented on routers. This means that an existing piece of technology can be used for dual purposes. Maintaining filter tables and access rules on multiple routers is not a simple task, and packet filtering of this sort is limited in what it can accomplish because it only examines certain areas of each packet. Dedicated packet-filtering firewalls are usually easier to configure and require less in-depth knowledge of protocols to be filtered or examined. One easy way that many packet filters can be defeated by attackers is a technique known as IP spoofing. Because these simple packet filters make all filtering decisions based on IP source and destination addresses, an attacker can often create a packet designed to appear to come from an authorized or trusted IP address, which will then pass through such a firewall unimpeded.

Application Gateways. Application-level filters, sometimes called assured pipelines, application gateways, or proxy servers, go beyond port-level filters in their attempts to control packet flows. Whereas port-level filters determine the legitimacy of the IP addresses and ports within packets, application-level filters are intended to provide increased assurance of the validity of packet content in context. Application-level filters typically examine the entire request for data rather than just the source and destination addresses. Controlled files can be marked as such, and application-level filters can be designed to prevent those files from being transferred, even within packets authorized by port-level filters. Of course, this increased level of scrutiny comes at the cost of a slower or more expensive firewall.

Certain application-level protocols commands that are typically used for probing or attacking systems can be identified, trapped, and removed. For example, SMTP is an e-mail interoperability protocol that is a member of the TCP/IP family and used widely over the Internet. It is often used to mask attacks or intrusions. Multipurpose internet mail extension (MIME) is another method that is often used to hide or encapsulate malicious code such as Java applets or ActiveX components. Other application protocols that may require monitoring include but are not limited to World Wide Web protocols such as HTTP, telnet, ftp, gopher, and Real Audio. Each of these application protocols may require its own proxy, and each application-specific proxy must be designed to be intimately familiar with the commands within each application that will need to be trapped and examined. For example an SMTP proxy should be able to filter SMTP packets according to e-mail content, message length, and type of attachments. A given application gateway may not include proxies for all potential application layer protocols.

Circuit-Level Proxies. Circuit-level proxies or circuit-level gateways provide proxy services for transport layer protocols such as TCP. Socks, an example of such a proxy server creates proxy data channels to application servers on behalf of the application client. Socks, uniquely identifies and keeps track of individual connections between the client and server ends of an application communication over a network. Like other proxy servers, both a client and server portion of the Socks proxy are required to create the Socks tunnel. Some Web browsers have the client portion of Socks included, whereas the server portion can be added as an additional application to a server functioning as a proxy server. The Socks server would be located inside an organization's firewall and can block or allow connection requests, based on the requested Internet destination, TCP port ID, or user identification. Once Socks approves and establishes the connection through the proxy server, it does not care which protocols flow through the established connection. This is in contrast to other more protocol-specific proxies such as Web proxy, which only allows HTTP to be transported, or WinSock Proxy, which only allows Windows application protocols to be transported.

Because all data goes through Socks, it can audit, screen, and filter all traffic in between the application client and server. Socks can control traffic by disabling or enabling communication according to TCP port numbers. Socks4 allowed outgoing firewall applications, whereas Socks5 supports both incoming and outgoing firewall applications, as well as authentication.

The key negative characteristic of Socks is that applications must be *socksified* to communicate with the Socks protocol and server. In the case of Socks4, this meant that local applications had to be recompiled using a Socks library that replaced its normal library functions. However, with Socks5, a launcher is employed which avoids *socksification* and recompilation of client programs that in most cases do not natively support Socks. Socks5 also uses a private routing table and hides internal network addresses from outside networks.

Application gateways are concerned with what services or applications a message is requesting in addition to who is making that request. Connections between requesting clients and service providing servers are only created after the application gateway is satisfied as to the legitimacy of the request. Even once the legitimacy of the request has been established, only proxy clients and servers actually communicate with each other. A gateway firewall does not allow actual internal IP addresses or names to be transported to the external non-secure network, except as this information is contained within content that the proxy does not control. To the external network, the proxy application on the firewall appears to be the actual source or destination, as the case may be.

Trusted Gateway. A trusted gateway or trusted application gateway seeks to relieve all the reliance on the application gateway for all communication, both inbound and outbound. In a trusted gateway, certain applications are identified as trusted and are able to bypass the application gateway entirely and are able to establish connections directly rather than be executed by proxy. In this way, outside users can access information servers and Web servers without tying up the proxy applications on the application gateway. These servers are typically placed in a demilitarized

zone (DMZ) so that any failures in the application servers will grant only limited additional access to other systems.

Proxies are also capable of approving or denying connections based on directionality. Users may be allowed to upload but not download files. Some application-level gateways have the ability to encrypt communications over these established connections. The level of difficulty associated with configuring application-level gateways versus router-based packet filters is debatable. Router-based gateways tend to require a more intimate knowledge of protocol behavior, whereas application-level gateways deal predominantly at the application layer of the protocol stack. Proxies tend to introduce increased latency compared with port-level filtering. The key weaknesses of an application-level gateway is their inability to detect embedded malicious code such as Trojan horse programs or macro viruses and the requirement of more complex and resource intensive operation than lower level filters.

Stateful Firewalls. Rather than simply examining packets individually without the context of previously transmitted packets from the same source, a stateful firewall stores information about past activities and uses this information to test future packets attempting to pass through. Stateful firewalls typically review the same packet information as normal simple packet filtering firewalls such as source address, destination address, protocol, port, and flags; however, they also record this information in a connection state table before sending the packet on. This table will have an entry for each valid connection established over a particular reference frame.

Some stateful firewalls keep sequence number information to validate packets even further, so as to protect against some session hijacking attacks. As each packet arrives to a stateful firewall, it is checked against the connection table to determine whether it is part of an existing connection. The source address, destination address, source port, and destination port of the new packet must match the table entry. If the communication has already been authorized, there is no need to authorize it again and the packet is passed. If a packet can be confirmed to belong to an established connection, it is much less costly to send it on its way based on the connection table rather than reexamine the entire firewall rule set. This makes a stateful firewall faster then a simple packet filtering firewall for certain types of traffic patterns, since the packet filtering firewall treats each connection as a new connection. Additionally, because there is a 'history' in the state tables, flags can be analyzed to ensure the proper sequence as in the TCP connection handshake, and the stateful firewall can drop or return packets that are clearly not a genuine response to a request.

As a result, stateful firewalls are better able to prevent some sorts of session hijacking and man-in-the-middle attacks. Session hijacking is very similar to IP spoofing, described earlier, except that it hijacks the session by sending forged acknowledgment (ACK) packets so that the victimized computer still thinks it is talking to the legitimate intended recipient of the session. A man-in-the-middle attack could be seen as two simultaneous session hijackings. In this scenario, the hacker hijacks both sides of the session and keeps both sides active and appearing to talk directly to each other when, in fact, the man-in-the middle is examining and potentially modifying any packet that flows in either direction of the session.

Internal Firewalls. Not all threats to a network are perpetrated from the Internet by anonymous attackers, and firewalls are not a stand-alone, technology-based quick fix for network security. In response to the reality that most losses due to computer crime involve someone with inside access, internal firewalls have been applied with increasing frequency. Internal firewalls include filters that work on the data link, network, and application layers to examine communications that occur only within internal networks. Internal firewalls also act as access control mechanisms, denying access to applications for which a user does not have specific access approval. To ensure the confidentiality and integrity of private information, encryption and authentication may also be supported by firewalls, even during internal communications. Figure 1 illustrates some of the aforementioned types of firewalls.

Enterprise Firewall Architectures

Previously described were different approaches to firewall architecture on an individual basis, but key decisions remain to be made regarding the number and location of these firewalls in relation to the Internet and a corporation's public and private information resources (Fig. 1). Each of the alternative enterprise firewall architectures explored in this section attempt to segregate three distinct networks or risk domains:

1. The Internet: contains legitimate customers and business partners as well as hackers
2. The DMZ, otherwise known as the screened subnet, neutral zone, or external private network: contains Web servers and mail servers
3. The internal private network, otherwise known as the secure network or intranet: contains valuable corporate information

Packet Filtering Routers. Packet filtering routers or border routers are often the first device that faces the Internet from an organization network perspective. These packet filtering routers first remove all types of traffic that should not even be passed to the firewalls. This process is typically fast and inexpensive because it involves only simple processes that are implemented in relatively low-cost hardware. Examples of removed packets include packet fragments, packets with abnormally set flags, time to live (TTL), abnormal packet length, or Internet control message protocol (ICMP) packets, all of which could potentially be used for attacks or to exploit known vulnerabilities and packet from or to unauthorized addresses and ports.

Dual-Homed Host Firewalls. In a dual-homed gateway or dual-homed host firewalls scenario, the application gateway is physically connected to the private secure network and the packet filtering router is connected to the nonsecure network or the Internet. Between the application gateway and the packet filter router is an area known as the screened subnet or DMZ. Also attached to this screened subnet are information servers, Web servers, or other servers that the company may wish to make available to outside users. All outside traffic still goes through the application gateway first, however, and then to the information servers.

TCP/IP forwarding is disabled, and access to the private network is only available through one of the installed proxies. Remote logins, if they are allowed at all, may only allowed to a gateway host.

Screened Host Firewalls. An alternative to the dual-homed gateway that seeks to relieve the reliance on the application gateway for all communication, both inbound and outbound, is known as a trusted gateway, screened host firewall, or trusted application gateway. In a trusted gateway, certain applications are identified as trusted and are able to bypass the application gateway entirely and establish connections directly rather than by proxy. In this way, outside users can access information and Web servers without tying up the proxy applications on the application gateway.

Screened Subnet Firewall (DMZ). Rather than using only the packet filtering router as the front door to the DMZ, a second firewall is added behind the packet filtering router to further inspect all traffic bound to or from the DMZ. The initial application gateway or firewall still protects the perimeter between the DMZ and the Intranet or secure internal network. The DMZ still contains mail, Web, and often e-commerce servers.

Multitiered DMZ. As e-commerce and e-business have proliferated, the need for e-commerce servers to access more and more secure information from database and transaction servers within the secure intranet has increased proportionately. As a result, the number of connections allowed through firewalls into the most secure areas of corporate networks has increased dramatically. In response to this phenomenon, the model of a multitiered DMZ has developed. Such a scenario really builds on the screened subnet firewall (DMZ) architecture by adding additional tiers to the DMZ, each protected from other tiers by additional firewalls. Typically, the first tier of the DMZ closest to the Internet would contain only the presentation or Web portion of the e-commerce application running on Web servers.

A firewall would separate that first tier of the DMZ from the second tier that would house the business logic and application portions of the e-commerce application typically running on transaction servers. This firewall would have rules defined to only allow packets from certain applications on certain servers with certain types of requests through from the first tier DMZ to the second-tier DMZ. The third (most secure) tier of the DMZ is similarly protected from the second tier by a separate firewall. The servers in the third-tier DMZ would be database servers and should contain only the data necessary to complete requested e-commerce transactions. Finally, as in the screened subnet firewall architecture, a firewall would separate the third-tier DMZ from the intranet, or most secure corporate network. Figure 2 illustrates some of the aforementioned enterprise firewall architectures.

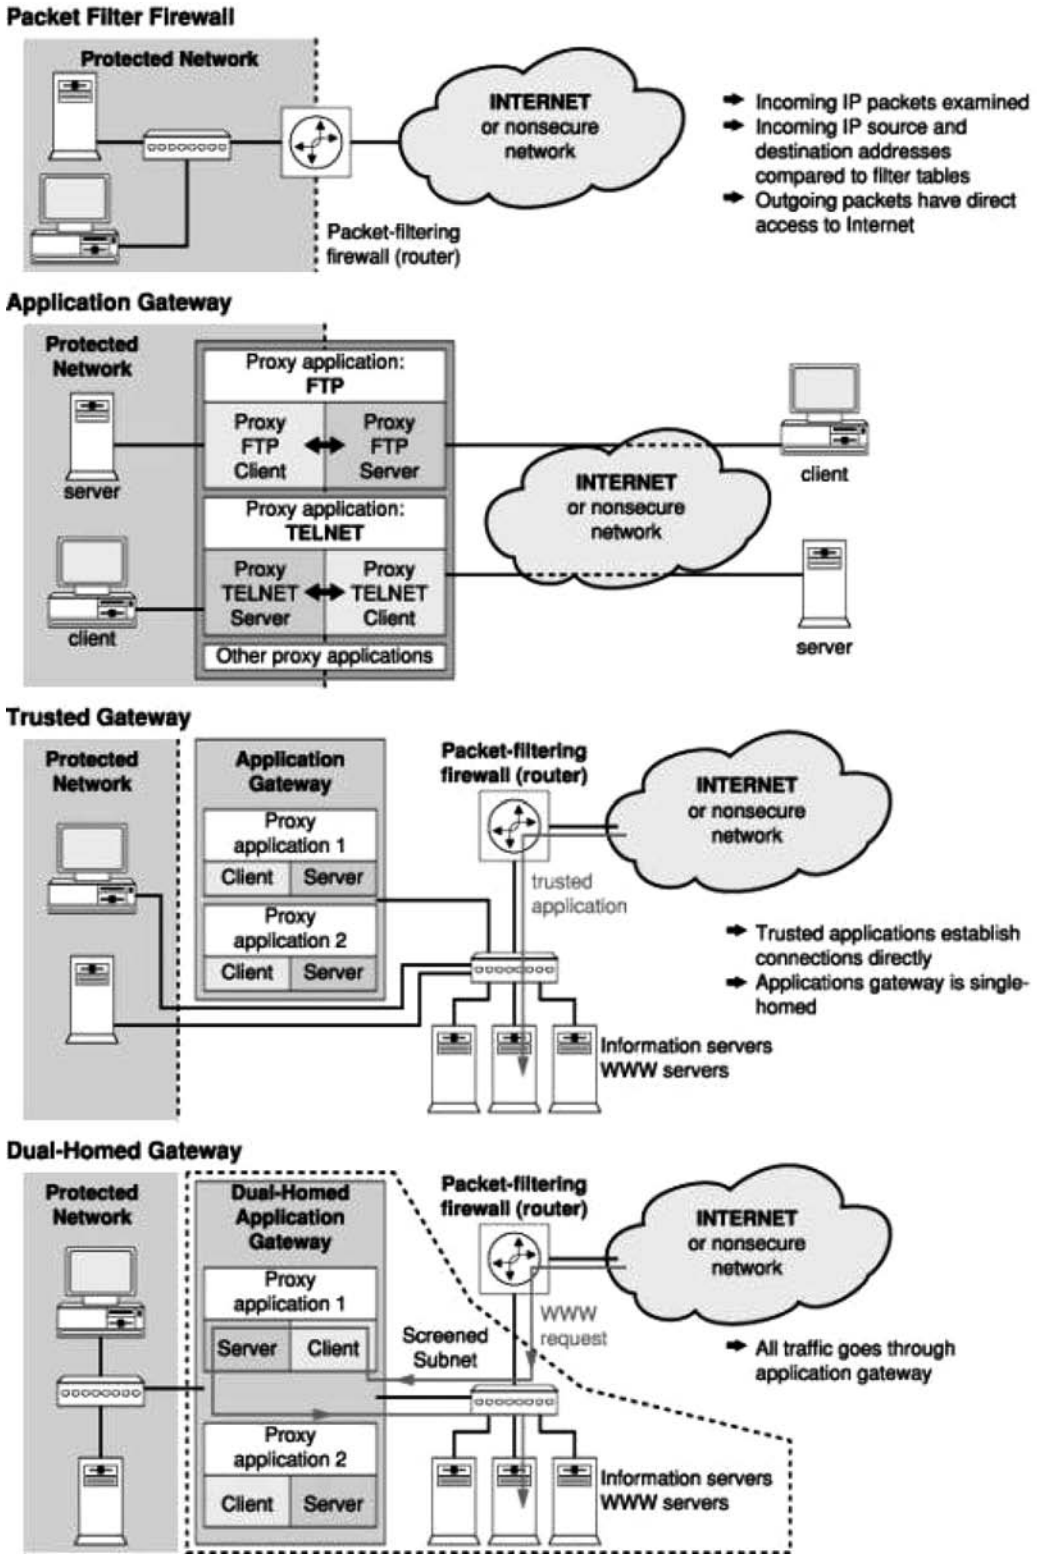

Fig. 1. Firewall types

Firewall Functionality and Technology Analysis

Commercially available firewalls usually employ either packet filtering or proxies as firewall architecture and add an easy-to-use graphical user interface (GUI) to ease the configuration and implementation tasks. Some firewalls even use industry standard Web browsers as their GUIs. Several certifying bodies are available to certify various aspects of firewall technology. As an example, one certifying body certifies the following:

- That firewalls meet the minimum requirements for reliable protection
- That firewalls perform as advertised
- That Internet applications perform as expected through the firewall

Table 1 summarizes some of the key functional characteristics of firewall technology.

Air Gap Technology

Some vendors try to assert the strength of their protection by using widely known terms such as *air gap* to characterize their protective mechanisms. One example of such a technology provides the same separation of the clean and dirty networks as firewalls. A hardware-based network switch

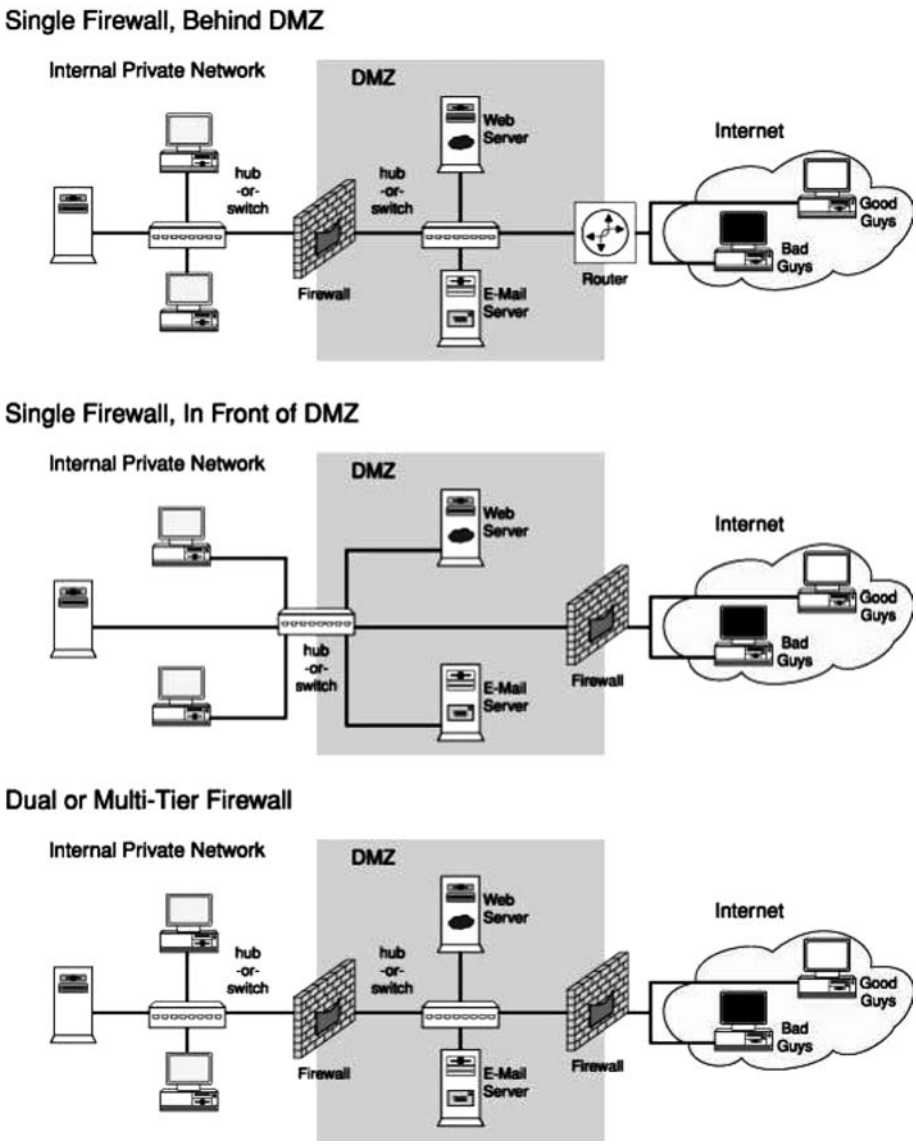

Fig. 2. Enterprise firewall architectures

is at the heart of this technology. he premise of creating a physical disconnection between the clean or secure network (Intranet) and the non-secure or dirty network (Internet) is accomplished by connecting a server on the Internet connection that will receive all incoming requests. This server will connect to an electronic switch that strips the TCP headers and stores the packet in a memory bank, and then the switch disconnects from the external server and connects with the internal server. Once the connection is made, the internal server recreates the TCP header and transmits the packet to the intended server. Responses are made in the reverse order. The physical separation of the networks and the stripping of the TCP headers remove many of the vulnerabilities in the TCP connection-oriented protocol. Of course this provides little additional protection over other firewalls at the content level because content-level attacks are passed through the so-called air gap and responses are returned.

There is a protective device that is highly effective at limiting information flow to one direction. The so-called *digital diode technology* is applied in situations in which the sole requirement is that no information be permitted to leak from one area to the other while information is permitted to flow in the other direction. An example would be the requirement for weather information to be available to military planning computers without the military plans being leaked to the weather stations. This sort of protection typically uses a physical technology such as a fiber-optic device with only a transmitter on one end and receiver on the other end to provide high assurance of traffic directionality.

Finally, the real and widely accepted meaning of an *air gap* is a physical separation that is effective at eliminating all communications across the media.

Small Office Home Office (SOHO) Firewalls

As telecommuting has boomed and independent consultants have set up shop in home offices, the need for firewalls for the SOHO market has grown as well. These devices are most often integrated with integrated services digital network–based multiprotocol routers that supply bandwidth on demand capabilities for Internet access. Some of these SOHO firewalls offer sophisticated features such as support for virtual private networks at a reasonable price. The most expensive of these costs less than $3,000 and some simpler filtering firewalls cost as little as $100. Some of these devices combine additional functionality such as network address translation, built in hub and switch ports, and load balancing in a combined hardware–software device known as a security appliance. Often DSL (digital subscriber line) or cable modems include firewall functionality because of their “always on” connection status.

Software-only solutions are also available. These products are installed on every computer and provide firewall-like functionality to each workstation. The benefits are that each workstation has an extremely inexpensive solution and that protection can be customized at the system level. The problem is that this requires all users to be firewall administrators for their computers, losing the economy of scale that was one of the original benefits associated with firewalls.

TABLE 1. SAMPLE FUNCTIONAL CHARACTERISTICS OF FIREWALL TECHNOLOGY[a]

Firewall Functional Characteristic	Explanation/Importance
Encryption	Allows secure communication through firewall Encryption schemes supported: DES Encryption key length supported: 40, 56, 128 bits
Virtual Private Network (VPN) Support	Allows secure communication over the Internet in a virtual private network topology VPN Security protocols supported: IPsec
Application Proxies Supported	How many application proxies are supported? Internet application protocols (HTTP, SMTP, FTP, telnet, NNTP, WAIS, SNMP, rlogin, ping traceroute)? Real Audio? How many controls or commands are supported for each application?
Proxy Isolation	In some cases, proxies are executed in their own protected domains to prevent penetration of other proxies or the firewall operating system should a given proxy be breached
Operating Systems Supported	Unix and Varieties, Windows NT,2000,XP
Virus Scanning Included	Because many viruses enter through Internet connections, the firewall is a logical place to scan for viruses
Web Tracking	To ensure compliance with corporate policy regarding use of the World Wide Web, some firewalls provide Web tracking software. The placement of the software in the firewall makes sense because all Web access must pass through the firewall. Access to certain uniform resource locators (URLs) can be filtered
Violation Notification	How does the firewall react when access violations are detected? Options include SNMP traps, e-mail, pop-up windows, pagers, reports.
Authentication Supported	As a major network access point, the firewall must support popular authentication protocols and technology
Network Interfaces Supported	Which network interfaces and associated data link layer protocols are supported?
System Monitoring	Are graphical systems monitoring utilities available to display such statistics as disk usage or network activity by interface?
Auditing and Logging	Is auditing and logging supporting? How many different types of events can be logged? Are user-defined events supported? Can logged events be sent to SNMP managers?
Attack Protection	Following is a sample of the types of attacks that a firewall should be able to guard against: TCP denial-of-service attack, TCP sequence number prediction, source routing and RIP attacks, EGP infiltration and ICMP attacks, authentication server attacks, finger access, PCMAIL access, DNS access, FTP authentication attacks, anonymous FTP access, SNMP access remote access remote booting from outside networks; IP, MAC and ARP spoofing and broadcast storms; trivial FTP and filter to and from the firewall, reserved port attacks, TCP wrappers, gopher spoofing, and MIME spoofing
Attack Retaliation/Counterattack	Some firewalls can launch specific counterattacks or investigative actions if the firewall detects specific types of intrusions
Administration Interface	Is the administration interface graphical in nature? Is it forms based?

([a]ARP = Address Resolution Protocol; DNS = Domain Name Server; EGP = Exterior Gateway Protocol; DES = Data Encryption Standard; FTP = File Transfer Protocol; HTTP = Hypertext Transfer Protocol; ICMP = Internet Control Message Protocol; IP = Internet Protocol; MAC = media access control; MIME = Multipurpose Internet Mail Extension; NNTP = Network News Transfer Protocol; RIP = Routing Information Protocol; SMTP = Simple Mail Transfer Protocol; SNMP = Simple Network Management Protocol; TCP = Transmission Control Protocol; WAIS = Wide Area Information Services.)

FIRMING AGENTS (Foods). Certain foodstuffs, such as apples, potatoes, and beans, tend to be rather fragile when subjected to processing operations prior to packaging (canning, freezing, etc.) and, if not treated in some way to retain their natural firmness to a relatively high degree, the texture of the final product will be disappointing (mushiness versus slight chewiness or crispness). Certain chemical substances can be added prior to or during processing to protect and retain natural firmness. These substances include: aluminum potassium sulfate, aluminum sodium sulfate, aluminum sulfate, calcium carbonate, calcium chloride, calcium citrate, calcium gluconate, calcium hydroxide, calcium lactobionate, calcium phosphate (monobasic), calcium sulfate, and magnesium chloride, among others.

Researchers have found that calcium lactate, in particular, can be an effective agent for preserving the firmness of apple slices during processing and prior to canning or freezing. Studies have shown that calcium salts participate in firming the tissues of various fruits and vegetables by forming calcium pectates. Calcium citrate is quite useful for firming peppers, potatoes, tomatoes, lima beans, and snap beans. Manufacturers of pet foods have found that from 1 to 2.5% monoglyceride contributes to the firming of pet foods, as well as aiding in the prevention of fat separation.

FIRN. Old snow that has become granular and compacted (dense) as the result of various surface metamorphoses, mainly melting and refreezing, but also including sublimation. The resulting particles are generally spherical and rather uniform. Firnification, the process of firn formation, is the first step in the transformation of snow into land ice (usually glacier ice). Some authorities restrict the use of firn to snow that has lasted through one summer, thereby distinguishing it from spring snow. Originally, the French term, "névé," was equivalent to the German term, "firn," but there is a growing tendency, especially among British glaciologists, to use "névés" for an area of firn, that is, generally for the accumulation area above or at the head of a glacier

FIRST-ORDER REACTION. See **Chemical Reaction Rate**.

FIRST-ORDER SYSTEM. A system whose performance characteristics are presented in the form of a first-order differential equation

$$r(t) = k_1 \frac{dC(t)}{dt} + k_2 \mathrm{TC}(t)$$

where r = system input
C = system output
t = time
k_1 and k_2 are coefficients

If both coefficients are constants, the Laplace transform should also be first order:

$$\frac{C(s)}{R(s)} = \frac{1}{k_1 S + k_2}$$

For simplicity, all initial conditions were assumed zero. The Figure 1 demonstrates graphically the time response of a first-order system which is subject to a step input, r_0.

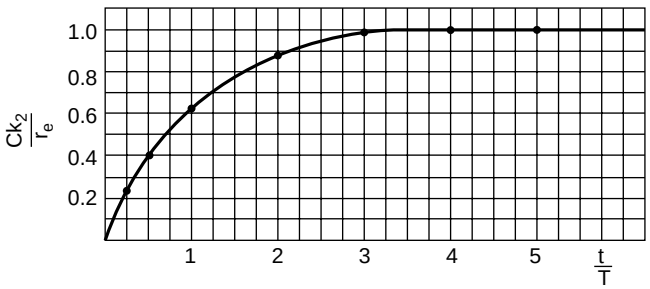

Fig. 1. Time response of a first-order system subjected to a step input. System time constant, $T = k_1/k_2$.

FIR TREES. Members of the family *Pinaceae* (pine family), these trees are of the genus *Abies* with the notable exception of the Douglas fir, which is of the genus *Pseudotsuga*. The term *fir* is used rather loosely and some dictionary definitions refer to the firs collectively as cone-bearing evergreens similar to the pine(s). Thus, botanists often use the term *true fir* to distinguish the true firs (also called *silver firs*) from other trees which may have the term fir associated in some way with their name. A case in point, shown in the following list, is the Chinese fir, which is not a member of the pine family, but rather it is of the *Taxodiaceae* (swamp cypress family). It should be pointed out that the Douglas fir is not a true fir as previously described. The Douglas fir, a truly magnificent tree, has the rather unattractive title of "false hemlock," the literal translation from the Latin *Pseudotsuga*. However, the full name, *Pseudotsuga menziesii*, honors the founder of the tree, explorer Menzies, who reported it in 1791. The fir trees are, of course, conifers. The general description of conifers is given in the entry on **Conifers**.

Some of the important species of fir trees are listed in Table 1. Others include:

Algerian fir	Abies *numidica*
Balsam of Gilead	*A. balsamea*
Caucasian fir	*A. nordmanniana*
Chinese fir	*Cunninghamia lanceolata* (Member of *Taxodiaceae* family)
Cilician fir	*A. cilicica*
Common silver fir	*A. alba*
East Himalayan fir	*A. spectabilis*
Flaky fir	*A. squamata*
Formosan silver fir	*A. kawakamii*
Forrest's fir	*A. delavayi forrestii*
Greek fir	*A. cephalonica*
Japanese fir	*A. firma*

TABLE 1. RECORD FIR TREES IN THE UNITED STATES[1]

Specimen	Circumference[2]		Height		Spread		Location

Siberian silver fir	*A. sibirica*
Sicilian red fir	*A. nebrodensis*
Spanish fir	*A. pinsapo*
Szechwan fir	*A. sutchuenensis*
Veitch fir	*A. veitchii*
West Himalayan fir	*A. pindrow*

Highlights of the distribution of fir trees in North America include: The balsam fir is the only native fir tree of the northeastern United States and Canada. It is found from Newfoundland and Labrador west to Hudson Bay, Michigan, and Minnesota, south to the high Alleghenies and into Virginia. It is found at high altitudes in the White Mountains of New Hampshire.

The closely related Fraser fir is found in the southern Alleghenies and in the mountains of Virginia, North Carolina, and Tennessee, commonly near the mountain summits, infrequently occurring below 4,000 feet (1,200 meters). Long a favorite tree for Christmas, the Fraser fir is now farmed rather extensively in North Carolina for the Holiday market. B.J. Jewell (*American Forests*, 26–27, December 1983) estimates that in 24 counties of western North Carolina, Fraser fir farming accounts for the largest source of agricultural income. Annual production now well exceeds two million trees. Two of the major problems for growers have been a reliable seed supply and the attack by the balsam woolly adelgid, an aphid that was introduced to America from Europe just after the turn of the century. Trees attacked by the aphids undergo dramatic internal changes — new wood growth on the tree's stem is harder and denser than normal. The dense, hard layer of new growth restricts the flow of water up through the tree and most infected trees die from this stress. Vulnerability is greatest when aphids invade during a period of drought.

The red fir and noble fir prefer the middle altitudes and are found in the Sierra and Cascade ranges of the west, northward from southern California into Canada. See Fig. 1. A variety of the red fir, the Shasta fir, is found in the area around Mount Shasta. The Colorado white fir ranges widely and is found from New Mexico northward into Oregon. The Alpine fir occurs on the Pacific slopes, ranging from New Mexico northward to the Pacific Northwest and into southeastern Alaska. The grand fir prefers lowlands or moist mountain slopes and ranges from the northern coast of California into southern British Columbia. The white fir is found on mountain slopes from Arizona and New Mexico northward through Nevada, Utah, the Cascade range of California, and into southern Oregon. The Pacific silver fir (sometimes simply called silver fir or *Amabilis* fir) prefers the country north of the Cascade range into Washington, British Columbia, and southern Alaska. The noble fir is also a Pacific mountain fir, ranging from the Cascade Mountains northward into Washington and Oregon. The Douglas fir is found in the Rocky Mountains and ranges northwestward to British Columbia and the Pacific Coast. The Rocky Mountain form has the varietal name of *Glauca*. Other forms range from Mexico up the coast and into Canada.

Probably the second tree in Europe in terms of height attained is the common European silver fir (*A. alba*). Other European firs include the Greek fir and the Spanish fir, the latter occurring along the Mediterranean. The Caucasian firs occur in the Caucasus Mountains, which interestingly are at the same latitude as northern California where so many of the firs thrive. Well-known firs of Japan include the Nikko and the Veitch, the latter occurring in part in the region of Mount Fuji. Maries' fir is also of Japan. Chinese fir trees include Forrest's fir and the Manchurian fir. Fir trees of the Himalayan region include both the East and West Himalayan firs. The Chinese "fir" (*Cunninghamia lanceolata*) is a major timber-producing tree in China, outdistanced only by bamboo. Details of the numerous species of firs, of course, cannot be detailed here. As representatives, however, the balsam fir and the Douglas fir are described briefly.

The balsam fir is a large stately tree with horizontal branches. The leaf is persistent and the cones erect. The fragrance is slightly tangy. The Canadian balsam produces turpentine. The wood is soft, but not considered of a high commercial grade. The weight is about 26 pounds per cubic foot (416.5 kilograms per cubic meter); specific gravity of 0.983 to 0.997.

Fig. 1. Noble fir located at Gifford Pinchot National Forest, Washington. (*U.S. Forest Service photo*.)

TABLE 2. ENGINEERING DATA ON WOOD FROM VARIOUS FIR TREES

Common Name for Species	Green Condition			Air-Dried (12% Moisture)		Maximum Crushing Strength (Parallel to Grain)		Maximum Tensile Strength Perpendicular to Grain)	
	Moisture Cotent (Percent)	Weight/ Cu.Foot (Pounds)	Weight/ Cu. Meter (Kilograms)	Weight/ Cu. Foot (Pounds)	Weight/ Cu. Meter (Kilograms)	(Psi)	(MPa)	(Psi)	(MPa)
Douglas fir, coast type	38	38	609	34	545	3860	26.6	300	2.1

The tree is widely used as a Christmas tree. Souvenir pillows are often stuffed with balsam needles. They are also used for packing boxes and for paper pulp.

Authorities consider the Douglas fir as one of the greatest of all trees. The oldest tree of this species still living is estimated at 1,300 years of age. This tree was discovered in 1825 by David Douglas, a visiting botanist from Scotland, on a trip to North America. The Douglas fir grows thick and lush at an altitude of about 8,000 feet (2,400 meters). The tree does not grow at altitudes higher than 10,000 feet (3,000 meters). It does well on thin mountain soil. The tree root system is shallow, the average roots going down only about four feet (1.2 meter).

Complex Biology of the Douglas Fir. For many years, tree biologists have puzzled over the successful survival of the Douglas fir in what has been described as a "crazy" climate and topography. The climate of the mountainous areas of the Pacific Northwest, for example, is fickle. As pointed out by J. Heinrichs (*American Forests*, 16–34, December 1980), "The coast seems to drip with constant rain that leaches nutrients out of the soil. Yet during the middle of the growing season — through July and August — much of the region is subject to drought. Despite the varied geography and undependable weather, the Douglas-fir has managed to extend itself over a tremendous area. It has the most extensive range of any commercial conifer in North America (British Columbia in the north; Mexico in the south). The tree can be found on bluffs overlooking the Pacific. Smaller, hardier varieties live up in the Rockies — as far east as Montana, Wyoming, Colorado, and New Mexico — where they are found as high as 11,000 feet (3355 meters), looking down on hardy ponderosa pine. The Douglas-fir reserves the choicest moist, well-drained habitat for itself, giving way only grudgingly to other competitive species at high elevations or northerly latitudes. Where rainfall is less than 25 inches (90 cm) a year, the Douglas fir lets the ponderosa pine take over. Where sites are poorly drained, the hardwoods come in. But within these extreme limits, say scientists, the great tree is 'omnipresent' in uniform stands."

The adaptability and survivability is generally attributed to the tree's unusually diverse set of genes, which result in very effective biological programming for both diversity and adversity. Early genetic research on the Douglas fir was started in the 1920s. With the advancing status of genetic engineering in the late 1980s, progress was be made at an accelerated rate. The large gene pool of the Douglas fir enabled it over eons of time to survive fires, drought, the Ice Age, and other ravages of nature. An individual Douglas fir can survive as long as 1325 years! Even with modern technology, however, scientists stress that the genetics of the Douglas fir is very complex and, of course, differs in trees from one forest area to the next. For example, the self-weeding process of the tree, presently poorly understood, has allowed the tree to adapt itself to widely different competitive conditions. For the immediate and pressing problems of reforestation, landowners in the Pacific Northwest continue to plant local seed from the best-looking trees in a cooperative program with the Forest Service. As pointed out by Heinrichs, "The program was established partly because of the failure of the original genetic attempts — based on seed orchards in which trees were grafted on top of each other. The Douglas fir has shown a strong reluctance to ride 'piggyback.' "

Utility of the Douglas Fir. The larger Douglas firs average about 80 to 100 feet (24 to 30 meters) in height. Usually the spread is about 55 to 60 feet (16.5 to 18 meters). In some specimens, the tree may rise 100 feet (30 meters) before the first branching is visible. The California Forestry Department has stated that "The Douglas fir supplies the world market with more products for use than any other species." Some of the logs cut for lumber are 10 feet (3 meters) in thickness and a large truck can handle only three at a time.

The bark, containing tannin, is a dark gray-brown color, resinous, and from 5 to 9 inches (12.7 to 22.9 centimeters) thick. The bark provides effective protection from insects, animals, and fire. The bark ridges are so deep that it is possible for a person to bury a fist in the crevice. The wood is soft, easy to work, light, strong, and firm. Large sheets of knot-free wood are obtained by sawing the base of older trees. Some of the many uses for this wood include heavy construction work, building of homes and factories, mine support props, telephone poles, bridge building, and ship docks. Strong, large decorative doors for homes and buildings are made from it on a large scale.

Tannin is recovered from the bark. Crushed bark is also used in the manufacture of acoustical tile and flooring.

Some engineering constants of the commercial wood from fir trees are given in Table 2.

FISCHER, EDMOND H. (1920–1992). Fischer was born in Shanghai, China and spent his early childhood studying in Geneva. He received degrees in biology and chemistry from the University of Geneva. He came to America in 1953 to work at Caltech but soon accepted a position at the University of Washington in their biochemistry department. Here he met Edwin Krebs and the two men started researching together. They discovered cellular enzymes could be activated and inactivated through phosphorylation-dephosphorylation by protein kinases.

Fischer and Krebs were awarded the Nobel Prize in Physiology or Medicine for their work on biological regulation mechanisms in 1992.

See also **Carbohydrates**.

J. M. I.

FISCHER, EMIL HERMANN (1852–1919). Emil Fischer was a German organic chemist and Nobel Prize winner who elucidated the structures of carbohydrates and proteins. Fischer was born in Euskirchen, near Bonn, and read chemistry at its university with A. Kekulé before working under A. von Baeyer at Strasbourg and then Munich. Following chairs at the Universities of Erlangen (1882–1885) and Würtzburg (1885–1892), he spent the remainder of his life at the University of Berlin. Fischer extended the work of Baeyer by the synthesis of complex organic compounds that closely resembled natural products, or their degradation products. Patient comparison of synthetic and natural molecules then enabled him to establish the exact constitutions and structures of sugars, enzymes, purines and proteins. He thereby laid the chemical foundations for biochemistry and the study of macromolecules and established a methodology of degradation and synthesis in natural products chemistry that remained in use until the 1950s, when physical and instrumental methods of structure determination became firmly established.

In 1875 he investigated a new group of organic hydrazine compounds and soon found them useful in the identification of aldehyde and ketone groups. Because phenylhydrazine ($C_6H_5NH-NH_2$) forms yellow crystalline osazones with definite melting points, he was able to unravel the structure of sugars and investigate their complicated epimerization (i.e. the change of configuration of one asymmetric carbon atom in a

sugar containing two or more such atoms). By the end of the nineteenth century he had determined the conformations of 16 aldohexoses and laid the foundations for carbohydrate chemistry. An investigation of the fermentation of sugars led him to the study of enzymes. He realized that they must possess a specific configuration to work on sugars with a specific stereoisometric form. His 'lock and key' model of enzyme action was announced in 1894 and proved extremely fruitful. A long-term study of the derivatives of uric acid, begun in 1881, extended Baeyer's earlier investigations. In 1897 Fischer established that biologically important molecules such as uric acid, xanthine, adenine and guanine were related to a heterocyclic nitrogenous base he named purine. Subsequently he synthesized many purines, including the barbiturate that was exploited commercially as Veronal. From 1899 onwards Fischer turned to the structure of proteins showing them to be composed from amino acids grouped in polypeptide chains. By 1916 he had synthesized over a hundred polypeptides. See also **Carbohydrates**; and **Sugar**.

He was the first German to be awarded the Nobel Prize for Chemistry in 1902 - in recognition of his syntheses of sugars and purines. With his black beard and pince-nez, Fischer was an awesome figure in the laboratory, which he ruled like an army general. But he was universally recognized as a great organic chemist. His over 350 research students included the Nobel Prize winners, O. Diels, H. Fischer, K. Landsteiner, F. Pregl, O. Warburg and A. Windaus. Despite ill health caused by the dangerous chemicals he worked with, he was an active patriot during World War I, organizing Germany's chemical and food supplies, but became disillusioned after the death of two of his sons on the battlefront. A surviving son, Hermann (1888–1960), who emigrated to America, became a distinguished biochemist. See also **Diels, Otto Paul Hermann (1876–1954)**.

W. H. BROCK, University of Leicester, Leicester, UK

FISCHER, ERNST OTTO (1918–). A German inorganic chemist who won the Nobel Prize for chemistry in 1973 with Geoffrey Wilkinson for their independent work on the chemistry of organometallic "sandwich compounds." He was the contributor to many publications on organometallic chemistry. His education and work were primarily in Munich.

FISCHER, HANS (1881–1945). The son of a dye chemist, Fischer studied chemistry at the University of Marburg, taking a doctorate in 1904, and medicine at the University of Munich, qualifying MD in 1908. Following positions in Munich (where he studied the bile pigment bilirubin, one of a class of naturally occurring color components called *porphyrins*), Innsbruck and Vienna. Fischer became head of the Institute of Organic Chemistry at the Technische Hochschule of Munich in 1921, where he remained for the rest of his life.

He investigated haemin, a pigment derived from blood haemoglobin and known to be chemically similar to bilirubin, which contains four pyrroles (pentagonal rings of four carbon atoms and one nitrogen atom). Systematic study of pyrrole chemistry led to the first synthesized porphyrin in 1926. Three years later Fischer synthesized haemin (which consists of four different pyrroles surrounding an atom of iron), for which he won the Nobel Prize for Chemistry in 1930. Turning next to chlorophyll, another porphyrin related to haemin (magnesium replacing iron), he identified its pyrrole rings but died before completing its synthesis, later achieved by his students. He synthesized bilirubin in 1944. Fischer's work on the chemistry of pyrroles was published in *Die Chemie des Pyrrols* (1934–1940).

Fischer was hard-working but secretive; he could appear forbidding but inspired devotion in his students. During the Second World War he became depressed, particularly after his laboratory was destroyed by bombing, and committed suicide in March 1945.

KATHERINE D.WATSON, University of Oxford, Oxford, UK

FISCHER-TROPSCH PROCESS. Synthesis of liquid or gaseous hydrocarbons or their oxygenated derivatives from the carbon monoxide and hydrogen mixture (synthesis gas) obtained by passing steam over hot coal. The synthesis is carried out with metallic catalysts such as iron, cobalt, or nickel at high temperature and pressure. The process was developed in Germany in 1923 by F. Fischer and H. Tropsch and was used there for making synthetic fuels before and during World War II. It has never been used for this purpose in the U.S., the only coal-to-gasoline conversion plant using this process is Sasol in South Africa, though the closely related Lurgi process is being used rather extensively in a number of locations. Easing of the petroleum crisis has tended to diminish conversion activity in the U.S.

FISCHER-TROPSCH SYNTHESIS. (Synthol process; Oxo synthesis). Synthesis of hydrocarbons, aliphatic alcohols, aldehydes, and ketones by the catalytic hydrogenation of carbon monoxide using enriched synthesis gas from passage of steam over heated coke. The ratio of products varies with conditions. The high-pressure Synthol process gives mainly oxygenated products, and addition of olefins in the presence of cobalt catalyst (Oxo synthesis) produces aldehydes. Normal-pressure synthesis leads mainly to petroleum-like hydrocarbons. See also **Oxo Process**.

FISHER'S *z* DISTRIBUTION. Fisher's z distribution was derived by R.A. Fisher in 1924:

$$P_z dz = \frac{2n_1^{n_1/2} n_2^{n_2/2}}{B\left(\frac{n_1}{2}, \frac{n_2}{2}\right)} \frac{e^{n_1 z}}{(n_1 e^{2z} + n_2)^{(n_1+n_2)/2}} dz, -\infty < z < \infty$$

$z = \frac{1}{2}\log s_1^2/s_2^2$, $B(n_1/2, n_2/2)$ is the Beta function, s_1^2 is an estimated variance with n_1 degrees of freedom and s_2^2 is an independent estimated variance with n_2 degrees of freedom. The z distribution is used in the analysis of variance. The z distribution becomes the normal curve in case $n_1 = 1$, $n_2 = \infty$ after the transformation $z = \frac{1}{2}\log \chi^2$, $0 \le \chi^2 < \infty$; It becomes the χ^2 distribution after the transformation $e^{2z} = \chi^2$, $n_1 = n$, $n_2 = \infty$, $0 \le \chi^2 < \infty$; and becomes Student's t distribution after the transformation $z = \frac{1}{2}\log t^2$, $n_1 = 1$, $n_2 = n$, $0 \le t < \infty$. In the limit as n_1 and $n_2 \to \infty$ in any manner whatever, the z distribution approaches normality with asymptotic mean $\frac{1}{2}(1/n_2) - (1/n_1)$ and asymptotic variance $\frac{1}{2}(n_1 + 1/n_1^2) + (n_2 + 1/n_2^2)$.

The z distribution has been extensively tabulated at the significance levels.

FISHES. There are two classes of fishes: (1) Cartilage fishes (Class *Chondrichthye*); and (2) bony fishes (Class *Osteichthyes*). Both of these classes are of the phylum *Chordata*.

The *Chondrichthyes*, sometimes also called elasmobranchs, include the sharks, rays, and skates. They are among the most generalized of the vertebrates that have complete vertebrae, movable jaws, and paired appendages. The term is derived from *chondros* (Greek for cartilage), and *ichthys* (fish).

The *Osteichthyes*, sometimes also referred to as *Pisces*, are considered the true fishes. They are cold-blooded vertebrates with a bony skeleton, jaws, four pairs of gills in a common cavity, skin with scales, and normally paired fins. The term is derived from *osteon* (Greek for bone; and ichthys, fish).

In general the fishes are characterized by several traits. (1) The skin is kept moist by glandular secretions and in many species is covered with scales. (2) The appendages are in the form of fins, used in swimming. (3) The gill slits persist in the walls of the pharynx and serve as the seat of the respiratory gills; and (4) the heart has only two principal chambers; an atrium or auricle and a ventricle.

It is estimated that there are about 25,000 species of fishes, found in approximately 36 orders, and some 400 families. In addition to the conventional anatomical and physiological bases (taxonomy) for classifying the fishes as shown in the accompanying tables, there are several other ways to classify or characterize the fishes which are helpful to understanding these animals. Much of this information is included, in specific entries in this volume, for well over 100 species. The species separately described are indicated by an asterisk in Tables 1 and 2.

In learning about a particular species, it is helpful to know as much as possible concerning: (1) the size — length, girth, and weight — from birth through adulthood, in terms of averages as well as records of maxima; (2) the longevity, ranging from days to many years; (3) performance parameters and temperament factors, such as speed and mobility, voracity versus docility, aggressiveness versus a desire to hide (burrowing,

TABLE 1. CLASSIFICATION OF THE CHONDRICHTHYES (Cartilage Fishes) (*indicates separate entry in this volume)

Order	Family	Example(s)
Selachii		Sharks*

	Rhinochimaeridae	Long-Nosed Chimaeras
	Callorhinchidae	Plow-Nosed or Elephant Chimaeras

etc.); (4) environmental needs or preferences which, in essence, determine habitat (or vice versa), including (a) fresh waters versus saline marine or brackish waters; (b) shallow, mid-depth, or deep waters; (c) clean versus turbid waters; (d) rushing, fast-moving waters versus quiet waters; (e) open seas, lakes, and rivers versus secluded coral reefs, rocks, gravel or muddy bottoms; (f) cold, temperate, or tropical waters; (5) diet and eating habits — carnivorous, herbivorous, omnivorous — and daily and seasonal feeding patterns; (6) reproduction and spawning habits — bearing of live young, ovipositors, egg layers — and migration patterns tied to spawning needs; (7) aside from spawning needs, other migratory habits and the general range of distances normally covered (entire life in a coral reef, pond, or river versus roving the open seas for hundreds, even thousands of miles); (8) relationships with other fishes of same or other species (schooling versus singular or small groups), as part of a community over and beyond seeking other fishes for food, or conversely, serving as prey (examples of symbiosis, such as the relationship between the remora and the shark, the role of cleaner fishes, relation of cucumber fish with sea cucumber, etc.); (9) unique characteristics or features, such as lack of red blood cells in the ice fishes, the true flying ability of the South American hatchet fishes, etc.); and (10) very important and of much interest, of course, is the interface between the various fishes and people — fishes as sources of food, oils, chemicals, and other useful items of commerce; as means for maintaining natural balances and preservation of desirable environments; and in the reactions of fishes to people-generated environments, in terms of vulnerability or hardiness to numerous kinds of pollution, etc.

Considering the foregoing, partial list of characterization factors and realizing that the parameters of each factor are in most cases very wide and that examples of species of fishes are found which fit the extremes as well as the full spectrum between these extremes, it becomes obvious that generalizations are difficult to put down. And, of course, it is not surprising to find so many different kinds of fishes.

Cartilage Fishes

Unlike the bony fishes, the skeleton of the cartilage fishes, as their name implies, is composed fully of cartilage, i.e., gristle. There are two postulates pertaining to the development of these fishes. The first is that the cartilage fishes are more primitive forms from which bony fishes later developed. A more recent and popular view is that the cartilage fishes are degenerate forms. The cartilage fishes (chondrichthyes), although of a relatively limited number of orders and families (Table 1) as compared with the bony fishes, embrace a wide variety of sizes, shapes, and other characteristics. A few of the representative forms are shown in Fig. 1. The whale shark is the largest of the chondrichthyes and, with exception of the whale, is the largest living vertebrate animal.

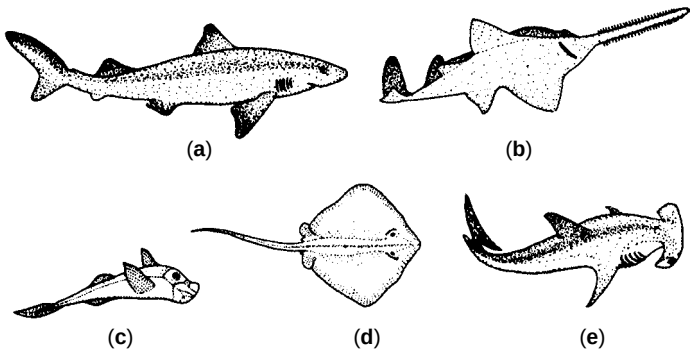

Fig. 1. Representative species of the chondrichthyes (cartilage fishes): (**a**) Shark; (**b**) sawfish; (**c**) ratfish; (**d**) sting ray; and (**e**) hammerhead shark. Examples are not to scale.

The skeleton of chondrichthyes is divided into two portions: (1) the axial skeleton which is comprised of the vertebral column and the skull; and (2) the appendicular skeleton composed of the fins and the pectoral and pelvic girdles which support the fins. The chondrichthyes are characterized by a spiral fold of mucus membrane within the intestine through which food moves in a corkscrew fashion. This is known as the spiral valve and may have a dozen or more "screwthreads." The valve assists in slowing the passage of food through the digestive system, allowing more time for absorption. These fishes have large livers, a gall bladder, pancreas, and spleen. As with all true fishes, only venous blood is pumped through the heart. Oxygenation occurs in the capillaries of the gills. Respiration is by means of the gills. The major differences between the chondrichthyes and the bony fishes are the cartilage construction of the skeleton and the absence of a number of organs and features, including air bladder, true scales, bones, and lungs.

The Bony Fishes

As will be noted by comparison of Tables 1 and 2, there are many more orders, families, and species of the bony fishes (osteichthyes) than the cartilage fishes. There is an extremely wide range of sizes, shapes, and characteristics and considerably more structural and physiological variation than displayed by the chondrichthyes. Unlike the chondrichthyes, the bony fishes have thousands of freshwater as well as marine or saltwater species. The external features of a representative bony fish are shown in Fig. 2 on p. 1407.

Some of the terms used to describe various organs and features of the bony fishes (some terms also applying to the chondrichthyes) include:

(*Adipose Fin*) — A fleshy fin without supporting spines, occurring behind the dorsal fin in some fishes.

(*Air bladder*) — A pouch found in some fishes, derived from the gut and filled with a mixture of gases, chiefly oxygen and nitrogen. It regulates the buoyancy of the body. Also called gas bladder; swimming bladder.

(*Barbel*) — A long, thin, tactile, and projecting "whisker" found extending from the head of some fishes.

(*Branchial Arteries*) — Blood vessels which lead both to and from the gills in fishes. Those which lead into the gills are the afferent branchials; those which lead out are the efferent branchials.

(*Canine Teeth*) — Proportionately large, sharp teeth, often conically shaped.

(*Caudal*) — With reference to the tail. The caudal fin is the tail fin.

TABLE 2. CLASSIFICATION OF THE OSTEICHTHYES (Bony Fishes)
(*indicates separate entry in this volume)

Order	Family	Example(s)
Cladistia	*Polypteridae*	Bichirs*
Chondrostei	*Acipenseridae*	Sturgeons*
	Polyodontidae	Paddlefishes*
Protospondyli	*Amiidae*	Bowfin*
Ginglymodi	*Lepisosteidae*	Gars*
Isospondyli	*Elopidae*	Tarpon*
	Albulidae	Bonefish or Ladyfish
	Alepocephalidae	Slickhead Fishes*
	Clupeidae	Herring* Sardines*
	Dorosomidae	Gizzard Shad*
	Dussumieriidae	Round Herring
	Chirocentridae	Dorab* (also Wolf Herring)
	Engraulidae	Anchovy*
	Chanidae	Milkfish*
	Salmonidae	Salmon*
		Trout*
	Coregonidae	Whitefishes*
	Thymallidae	Grayling*
	Osmeridae	Smelts*
		Capelin*
	Galaxiidae	Galaxiids*
	Gonostomatidae	Brisstlemouths*
	Sternoptychidae	Hatchet Fishes*
	Chauliodontidae	Viper Fishes*
	Osteoglossidae	Bony Tongues*
	Pantodontidae	Butterfly Fish*
	Hiodontidae	Mooneye
	Notopteridae	Featherbacks*
	Mormyridae	Mormyrids*
	Gonorhynchidae	Sandfish (also Beaked Salmon)
Haplomi	*Esocidae*	Pike* (includes Pickerel and Muskellunge)
	Umbridae	Mud Minnows
	Dalliidae	Blackfish*
Iniomi		Iniomous Fishes*
	Synodidae	Lizard Fishes
	Aulopidae	Thread-Sail Fishes
	Chlorophthalmidae	Greeneyes
	Ipnopidae	Grid-Eye Fishes
	Bathypteroidae	Spider Fishes
	Myctophidae	Lantern Fishes
	Harpodontidae	Bombay Duck
	Paralepididae	Barracudinas
	Scopelarchidae	Pearleyes
	Evermannellidae	Saber-Tooth Fishes
	Alepisauridae	Lancet Fishes
	Omosudidae	Hammerjaw
	Anotopteridae	Javelin Fish
Giganturoidea	*Giganturoidea*	Deep-Sea Giganturid Fishes
Lyomeri		Deep-Sea Gulper Eels
Ostariophysi	*Characidae*	Characids* (includes Piranha)
	Gymnotidae	Gymnotid Eels* (includes Electric Eel and Knifefishes)
Group: *Cypriniformes*		Bitterling*
	Cyprinidae	Carp* (includes Minnows)
	Catostomidae	Suckers*
	Cobitidae	Loaches*
	Gyrinocheilidae	Gyrinocheilids
	Homalopteridae	Hillstream Fishes
Suborder: *Siluroidea*		Catfishes*
	Doradidae	Doradid Catfishes
	Callichthyidae	Callichthyid Catfishes
	Loricariidae	Plecostomus*
	Aspredinidae	Banjo Catfishes
	Ariidae	Ariid Marine Catfishes
	Plotosidae	Plotosid Marine Catfishes
	Clariidae	Clariid Catfishes
	Siluridae	Silurid Catfishes
	Pimelodidae	Pimelodid Catfishes
	Bagridae	Bagrid Catfishes
	Trichomycteridae	Parasitic Catfishes
	Ictaluridae	North American Catfishes
	Schilbeidae	Schilbeid Catfishes
	Mochocidae	Upside-Down Catfishes
	Malapteruridae	Electric Catfish
Apodes		Eels*
	Anguillidae	Fresh Water Eels
	Simenchelidae	Parasitic Snubnosed Eel
	Muraenidae	Moray Eels
	Ophichthidae	Snake Eels
	Nemichthyidae	Snipe Eels
	Synaphobranchidae and Serrivomeridae	Deep-Sea Eels
	Congridae	Conger Eels
	Moringuidae	Worm Eels
Heteromi		Deep-Sea Spiny Eels
Synentognathi		
	Belonidae	Needlefishes
	Hemiramphidae	Halfbeaks
	Scomberesocidae	Sauries
	Exocoetidae	Flying Fishes*
Microcyprini		
	Amblyopsidae	Blind Fish*
	Cyprinodontidae	Egg-Laying Topminnows
	Poeciliidae	Viviparous Topminnows*
	Goodeidae	Goodeids
	Anablepidae	Four-Eyed Fishes*
	Jenynsiidae	Jenynsiids
	Adrianichthyidae	Andrianichthyids
Salmopercae		
	Percopsidae	Troutperch
	Aphredoderidae	Pirateperch
Solenichthys		Tube-Mouthed Fishes
	Syngnathidae	Pipefishes*
		Seahorses*
	Solenostomidae	Ghost Pipefishes
	Indostomidae	Indostomids
	Centriscidae	Shrimpfishes
	Macrorhamphosidae	Snipefishes
	Fistulariidae	Cornetfish
	Aulostomidae	Trumpetfishes
Anacanthini	*Gadidae*	Codfishes*
	Merlucciidae	Hake*
	Coryphaenoididae	Deep-Sea Rattails or Grenadiers
Allotriognathi		
	Lampridae	Opah*
Berycomorphi	*Holocentridae*	Squirrelfishes* (also Soldierfishes)
	Berycidae	Alfonsinos
	Anomalopidae	Lantern-Eye Fishes
	Polymixiidae	Barbudos
	Monocentridae	Pinecone Fishes
Suborder: *Xenoberyces*		Gibber, Prickle, Bigscale, and Whalefishes
Zeomorphi		John Dories*
	Antigoniidae	Boarfishes
	Grammicolepidae	Grammicolepids
Percomorphi		Perchlike Fishes
Suborder: *Percoidea*		
	Serranidae	Bass* (includes Groupers)
	Theraponidae	Tigerfishes
	Kuhliidae	Aholeholes
	Centrarchidae	Sunfishes*
	Priacanthidae	Catalufas or Bigeyes
	Apogonidae	Cardinal Fishes
	Percidae	Perches and Darters* (includes Walleyes)
		Redfish*
	Malacanthidae	Blanquillos
	Pomatomidae	Bluefish
	Rachycentridae	Cobia*
	Carangidae	Carangids* (includes Cavallas. Jacks. Pompanos) Scad*
	Coryphaenidae	Dolphins*
	Centropomidae	Robalos (Snook and Glassfish)
	Lutianidae	Snappers*
	Nemipteridae	Nemipterids
	Lobotidae	Tripletails

(*continued*)

TABLE 2. (*Continued*)

Order	Family	Example(s)
	Leiognathidae	Slipmouths
	Gerridae	Mojarras
	Pomadasyidae	Grunts*
	Sciaenidae	Croakers*
	Mullidae	Goatfishes or Surmullets
	Lethrinidae	Lethrinids
	Sparidae	Porgies* (includes Sea Breams)
	Monodactylidae	Fingerfishes
	Toxotidae	Archerfishes
	Kyphosidae	Rudderfishes
	Girellidae	Nibblers
	Platacidae	Batfishes
	Ephippidae	Spadefishes
	Scatophagidae	Scats
	Chaetodontidae	Angelfishes* (includes Butterfly Fishes)
	Nandidae	Leaf Fishes and Nandids
	Cichlidae	Cichlids*
	Cirrhitidae	Hawkfishes
	Embiotocidae	Surfperches
	Pomacentridae	Damselfishes
	Labridae	Wrasses*
	Scaridae	Parrotfishes*
	Trichodontidae	Sandfishes
	Opisthognathidae	Jawfishes
	Trachinidae	Weeverfishes*
	Trichonotidae	Sand Divers
	Kraemeriidae	Sand Lances
	Uranoscopidae	Electric Stargazers
	Dactyloscopidae	Sand Stargazers
	Chaenichthyidae	Ice Fishes*
Suborder: *Acanthuroidea*		
	Zanclidae	Moorish Idol
	Acanthuridae	Surgeonfishes*
Suborder: *Siganoidea*	*Siganidae*	Rabbitfishes*
Suborder: *Trichiuroidea*		
	Trichiuridae	Cutlass Fishes and Hairtails*
	Gempylidae	Deep-Sea Snake Mackerels or Escolars
Suborder: *Scombroidea*		
	Scombridae	Mackerels*
		Tunas*
	Istiophoridae	Billfishes* (includes Marlins, Sailfishes, and Spearfishes)
	Xiphiidae	Swordfish (described under Billfishes)
	Luvaridae	Louvar
Suborder: *Gobioidea*	*Eleotridae*	Sleepers
	Gobiidae	Gobies*
	Taenioididae	Eel Gobies
	Rhyacichthyidae	Loach Goby
	Callionymidae	Dragonets*
Suborder: *Blennioidea*		Blennies*
	Blenniidae	Scaleless Blennies
	Clinidae	Scaled Blennies or Klipfishes
	Stichaeidae	Pricklebacks
	Pholidae	Gunnels
	Anarhichadidae	Wolf Fishes and Wolf Eels
	Zoarcidae	Eelpouts
Suborder: *Ophidioidea*		
	Brotulidae	Brotulids
	Ophidiidae	Cusk Eels
	Carapidae	Cucumber and Pearl Fishes
Suborder: *Stromateoidea*		Butterfishes*
Suborder: *Anabantoidea*	*Anabantidae*	Labyrinth Fishes*
Suborder: *Channoidea*	*Channidae*	Snakeheads
Suborder: *Mugiloidea*		
	Sphyraenidae	Barracuda*
	Atherinidae	Silversides*
	Mugilidae	Mullets*
Suborder: *Phallostethoidea*	*Phallostethidae*	Phallostethids
Suborder: *Polynemoidea*	*Polynemidae*	Threadfins
Scleroparei		
	Scorpaenidae	Scorpionfishes and Rockfishes
	Triglidae	Sea Robins*
	Peristediidae	Armored Sea Robins
	Cottidae	Sculpins*
	Rhamphocottidae	Grunt Sculpin
	Agonidae	Sea Poachers and Alligator Fishes
	Liparidae	Snailfishes
	Cyclopteridae	Lumpsuckers
Suborder: *Datcylopteroidea*	*Dactylopteridae*	Gurnards*
Thoracostei		Sticklebacks and Tubenose
	Aulorhynchidae	Tubenose
Hypostomides	*Pegasidae*	Sea Moths*
Heterosomata		Flatfishes*
	Bothidae	Left-Eyed Flounders
	Pleuronectidae	Right-Eyed Flounders
	Soleidae	Soles
	Cynoglossidae	Tongue Soles
Discocephali	*Echeneidae*	Remoras* (or Suckerfishes)
Plectognathi		
	Balistidae	Triggerfishes
	Tetraodontidae	Puffers*
	Canthigasteridae	Sharp-Nosed Puffers
	Diodontidae	Porcupine Fishes* (including Burnfishes)
	Ostraciontidae	Trunkfishes
	Molidae	Ocean Sunfishes
Malacichthys	*Icosteidae*	Ragfishes
Xenoptergyii	*Gobiesocidae*	Clingfishes
Haplodoci	*Batrachoididae*	Toadfishes and Midshipmen
Pediculata		Anglerfishes*
	Lophiidae	Goosefishes or Monkfishes
	Antennariidae	Frogfishes
	Ogocephalidae	Batfishes
Suborder: *Ceratioidea*		Deep-Sea Anglers
Opisthomi	*Mastacembelidae*	Spiny Eels
Synbranchii	*Synbrachidae*	Swamp Eels
Actinistia		Coelacanths*
Dipneusti		Lungfishes*

(*Caudal Peduncle*)—That portion of the body of a fish located just forward of the tail fin.

(*Dorsal Fin*)—Located on the back of the fish—the main fin on the back.

(*Fin*)—A broad thin appendage, primarily an organ of stabilization, steering, and locomotion. The two principal kinds of fins are the median and the paired. Median fins extend from the body along the median line of the dorsal surface, around the caudal end as the tail fin or tail, and forward as far as the vent. Paired fins include a pectoral pair attached to the pectoral girdle of the skeleton and the pelvic pair attached to the pelvic girdle. All fins are supported by bony (osteichthyes) fin rays or by cartilaginous (chondrichthyes) fin rays.

The median fin is broken up in most fishes to form separate dorsal fins and a ventral anal fin in addition to the caudal fin or tail. A caudal division of the dorsal portion is sometimes developed into the fleshy adipose fin. The tail fin may be heterocercal or homocercal. The former type has the end of the vertebral column extending into or toward its dorsal margin; while the latter is evenly developed above and below the skeletal axis.

Paired fins are variously modified to form sensory lobes or supporting structures.

(*Gill*)—The respiratory organ of aquatic animals. See also **Gill**.

(*Gular Plate*)—Only present in some fishes and located under the throat, a hard plate protecting the under portion of the throat.

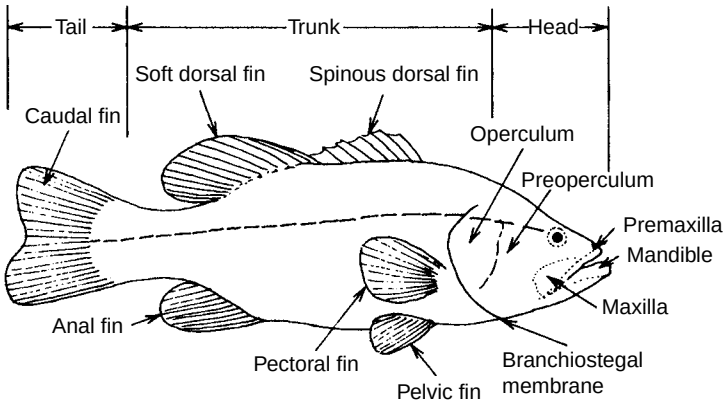

Fig. 2. Principal features of a "typical" bony fish. In this case, a largemouth black bass.

(*Lateral Line*) — A longitudinal line, often quite apparent, on each side of the body of a fish. Contains vibration and pressure sensing organs.

(*Lateral Line Organs*) — Sensory organs located on the head and in a line (along the lateral line). They are unlike the sensory organs of terrestrial vertebrates, but are assumed to perceive vibrations of low frequency.

(*Mandible*) — Lower jaw.

(*Maxilla*) — The largest of the bones forming the upper jaw.

(*Milt*) — The sperm of fishes.

(*Operculum*) — Covering over the gills.

(*Oviparous*) — Egg-laying.

(*Ovoviviparous*) — Production and hatching of eggs within the female [and that hatch within the female] with the young being born alive.

(*Parasphenoid*) — A dermal bone supporting the roof of the mouth in fishes.

(*Pectoral Fins*) — A pair of fins which are attached to the shoulder girdle.

(*Pelvic Fins*) — The pair of hind fins. Also called ventral fins.

(*Photophore*) — A light-producing organ.

(*Premaxilla*) — Bones of the upper jaw (front).

(*Preoperculum*) — Anterior cheek bone.

(*Pseudobranchia*) — A small respiratory structure on the inner surface of the operculum in certain fishes; spiracular or vestigal hyoidean gill, serving as a supplementary gill.

(*Roe*) — Fish eggs.

(*Rostrum*) — A snout. The term is applied particularly to the elongated snouts of certain fishes.

(*Vent*) — External opening of the intestine. Anus.

(*Viviparous*) — Young are born alive.

Some Characteristics of the Fishes

Although fishes are found in practically all unpolluted waters of the earth ranging from the warm water of the tropics to the very cold waters of the arctic and antarctic, most species prefer a relatively narrow span of water temperature. Most species are sensitive to temperature changes and usually cannot tolerate rapid fluctuations of over 12 to 15 °F (~7–8 °C).

Water Balance. This is critical to fishes. In the case of salt water fishes, the body juices are less saline than the outside water and the fishes are consequently in the ever present danger of dehydration. Saltwater fishes must drink copious amounts of water to compensate for that lost through the gills and skin. Some accumulated salt is passed through the digestive tract and excreted. In some fishes, special gill cells aid in returning the water back to the sea. In contrast, the body juices of the freshwater fish are more saline than its water environment. Thus, freshwater fishes are in the ever present danger of swelling and thus they do not drink. The water coming in through the gills and skin passes through the kidneys and is carried away as waste. Freshwater fishes generally produce copious quantities of urine.

Locomotion. A fish swims by pushing water aside. This is done by creating a wiggling motion through the use of the head, tail, and to some degree, other fins, depending upon the species of fish. While difficult to detect, the movements, forward or backward, are essentially snakelike. The various disk-shaped fishes and triggerfishes make important use of their pectoral fins in achieving motions. In most other fishes, the fins serve various steering and guidance functions. Stabilizing actions are the principal functions of the dorsal and pectoral fins, the pectoral in particular being used for balancing and turning. Pelvic fins usually serve as stabilizers. The tail fin usually performs a number of functions, including propulsion, steering, and stabilizing. In fast-swimming, streamlined fishes, the dorsal and anal fins may fold back, essentially retracting into grooves, thus becoming flush with the body. However, for every generalization of the type just described, there are exceptions. Skates and rays, for example, obtain most of their locomotion by way of much enlarged side fins making them appear as though flying through the water.

The shapes of representative chondrichthyes were given in Fig. 1. Representative shapes of osteichthyes are given in Fig. 3.

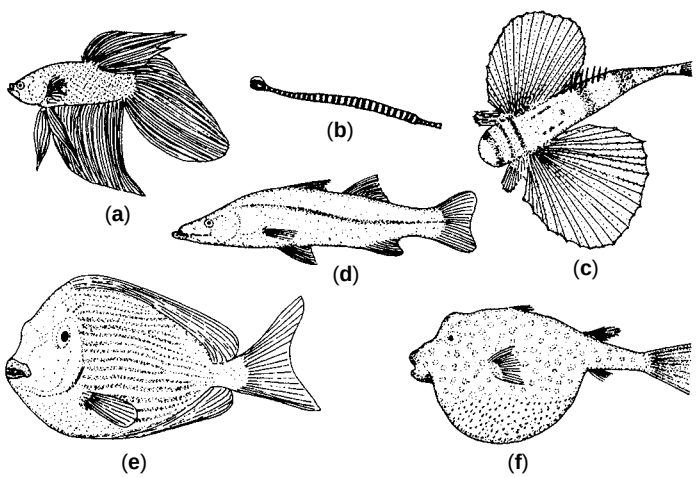

Fig. 3. Representative species of the osteichthyes (bony fishes): (**a**) Siamese fighting fish (fresh water); (**b**) banded pipefish (marine); (**c**) flying gurnard (marine); (**d**) snook (marine, occasionally fresh water); (**e**) striped surgeonfish (marine); and (**f**) southern puffer (marine) shown after self-inflation with air. Examples are not to scale.

Buoyancy. This is accomplished in most fishes by means of a gas bladder. This is a gland-lined airtight sac in the gut of the fish. The glands remove gases from the bloodstream of the fish and direct the gases to the bladder. By regulating the amount of gas in the bladder, the fish may select whatever depth may be desired. Regulation usually is quite rapid and operable from the surface to a depth of about 1,200 feet (360 meters). If a hooked fish is brought to the surface at too rapid a rate, the balloon may burst, causing the stomach to be forced out of the mouth. The gas or air bladder as it is commonly called varies in size in proportion to the fish. Where the bladder is small in comparison with the size of the fish, vertical adjustments to pressure usually are accomplished more readily. Some fishes do not have air bladders (for example, mackerels) and, consequently, to maintain a given level in the water, these fishes must constantly move, lest they sink.

Protection. This is achieved by a flexible armor in the form of scales. These vary in shape and construction. As do the fingernails in humans

grow as the person grows in size, so do the scales of a fish. Although the chondrichthyes are not formally recognized as having skin with scales, they do have primitive placoid scales, which may be described as toothlike, but of very small dimensions so that the result is that a shark, for example, has an outer surface something like sandpaper. Primitive fishes, such as the garpike, have ganoid scales. Each scale is shaped like a diamond and is attached to adjacent scales by joints. Ganoin, a material that imparts a glossy ivory-like appearance to the fish, is the outside coating for these scales. Thus the scales are well held together on the under and outer surfaces.

Ctenoid and cycloid scales are the most commonly found types among the bony fishes. Both scales are roughly circular in shape with a fine design appearing something like the annual-ring patterns in the cross section of a tree trunk. However, one side of the "circle" is more like a bump. In the ctenoid scales, this bump has a comblike edge; in the cycloid scales, the bump is smooth. Thin, lightweight, and flexible, these scales are arranged in neat, overlapping rows.

Vision. The seeing apparatus of most fishes parallels human vision in many respects. It is interesting to note, however, that surface-feeding fishes must allow for refraction of light as it bends at the air-water interface. An important difference in the structure of eyes in most fishes is the result of very limited light under water and the absence of rapidly changing amounts of light. Hence, fishes require no eyelids and they do not require a sophisticated iris to regulate the light passing into the eye. Fish eyes are spherical and essentially rigid. The lens is filled with water. Consequently light passing from outside is not refracted at the lens interface. With this spherical structure, theoretically a fish should be able to focus well, but this is debatable. Fish have monocular vision, that is, objects on the right are sensed by the opposite side of the brain and conversely with objects at the left. With eyes on each side of the head, more than one direction can be noted at any one time. See also **Four-Eyed Fishes**. Studies indicate that most fishes have rudimentary color conception, but it is not believed that, in the fish's world of largely subdued greenish-blue tones, color plays an important role, but this requires further study. Sportsmen certainly believe that color is important in the hooking of various fishes, such as trout. It is known, of course, that fishes do recognize patterning, if not color. The example is often given of the vertically-striped pilot fish, less than 12 inches (0.3 meter) in length, that can safely accompany a shark. It is generally assumed that the shark may recognize the pilot fish by its stripes. Color per chance may play a role in warning fishes of certain highly-colored poisonous fishes. Coloration certainly is used to advantage by many fishes in their ability to blend in with their backgrounds, changing color as well as patterning.

The vision process of fishes is quite complex and for greater detail, the reader is referred to the Davison (1969); Endler (1980); Levine (1979, 1980); McFarland (1975); and Munz (1977) references listed at the end of this entry.

Sound. It is only within the past decade or two that concerted efforts have yielded scientific information on how fishes make sounds and how they detect sounds. Certain fundamentals have been known for a long time, but the intricate mechanisms involved have been poorly understood. At one time, authorities disagreed on the importance and indeed the existence of acoustic systems in many species of fishes. It has been established that all or most fishes have a hearing sense, far more refined in some species than in others.

It is well understood that considerable background noise (the noise created by swimming and, in particular, by thousands of companions in schooling fishes, as well as the noise from wave action near the surface) must play a major role in the hearing process, in particular how this background noise is sorted out from the noise of predators. It has been shown that many species cannot respond to sounds above about a few hundred cycles per second (Hz). However, clupeoid and ostariophysine fishes can respond to higher frequencies.

Sound can be presented to fishes in two fundamental ways: (1) a sinusoidal change in pressure, as that which can be measured by a hydrophone; and (2) a back-and-forth motion of the water, expressed as particle displacement or particle velocity, which is more difficult to detect, requiring sensors in three planes. Pressure and particle motion are related to each other and to the distance of the sound source. Particle motion can give information about the direction of the sound source; pressure cannot.

As pointed out by Blaxter (1980), particle displacement is sensed in some species by mechanoreceptors, located in the acousticolateralis system that comprises the inner ear and the lateral line. In both the ear (labyrinth) and the lateral line, the basic receptor is the neuromast organ, consisting of a group of sensory cells, each with a bundle of ciliary hairs embedded in a gelatinous cupula. The neuromasts have directional qualities. Many species of teleost have a swimbladder that responds to sound pressure by pulsating in sympathy with the passing compressions and rarefactions. The sound pressure will then be reradiated as displacements, thus creating a secondary near-field within the fish that can stimulate the displacement receptors.

For a more detailed review of this topic as of the early-1980s, the paper by Blaxter (1980) is suggested. Further interesting papers include Hawkins (1973); Hoar and Randall (1971); Schuijf and Hawkins (1976); and Travolga et al. (1981), listed at the end of this entry.

Nervous System. Most fishes have large numbers of nerve organs in their skin, as well as barbels, which can be used as feelers. Hence, they are equipped with a sense of touch. The fish nervous system consists of brain, spinal cord and nerves. The elongated brain has five segments: Forebrain, diencephalon, midbrain, cerebellum, and brain stem. The spinal cord proceeds from the brain stem down to the tail. It is a round cord, which is enclosed by the vertebral column. Twelve nerve pairs (the "cranial nerves") are sent from the brain to the sensory organs of the head and to the head musculature. The spinal cord transmits nerve impulses from the brain and, on the basis of the number of vertebrae, sends signals to an equal number of spinal nerves with a ventral motor root and a dorsal sensory root. The latter are associated with the sympathetic nervous system. The nerve system runs in the form of two fine nerve strands underneath and along the vertebral column. In cartilaginous fishes, the forebrain is highly developed and the halves are not completely divided. All other fishes have clearly divided brain halves, which in lungfishes are large, and in teleost fishes are small and supplied with olfactory lobes. The brain weighs about 1:1300 of the body weight (as in a gar, for example). The brain cortex is, in contrast to higher vertebrates, convoluted to just a small degree.

One of the best-developed senses in the fish is that of smell. A shark's ability to detect blood from long distances is well established. With the exception of the lungfishes, fishes do not have taste buds in their mouths. However, such organs could be located elsewhere. From the gulping eating habits of most fishes, however, it would appear that taste is not a consideration.

The pain threshold is very high in fishes, with no physiological component — as presently considered by most investigators. Fish have no equivalent to the human cortex where nerve impulses are integrated. The performance of injured fishes bears out these observations.

Musculature. The muscle comprises a large part of the fish body. Its arrangement on the skeleton permits the very flexible fish movements. On the head is the facial musculature of the jaw and gill arches. The chewing muscles, the muscle groups of the gill cover, and the mandibular and gill arch muscles together form an independent muscle group proceeding from the sides. The strong lateral trunk muscles for propulsion of the fish are developed from the vertebrae and extend from the back of the head to the root of the caudal fin and are symmetrical on both sides of the vertebral column. They consist of numerous muscle segments, one behind the other, which are separated by fine connective tissue partitions; they also consist of a dorsal part and a ventral portion, between which lies a wall of connective tissue. Corresponding to the arrangement of the axial skeleton, each part falls into small muscle packets (*myomeres*). The musculature is held to the vertebral column by connective tissue partitions (*myocommata*). The fin musculature develops from split off trunk musculature. Here the depressors of the fin rays, which fold them together, are differentiated from the lifters that spread the fins out.

Respiration. Breathing occurs by internal gills, which lie between the pharynx and body wall in pockets and take up oxygen dissolved in the water. The gills are thin layers of skin with blood vessels, which are free in sharks and protected by a gill cover in teleost fishes. Water enters the mouth and is expelled through the gills. It thereby runs over or through the gills, the surface of which is permeated by blood vessels. The blood takes up oxygen and releases carbon dioxide. The surface area of the gills of a carp measures about 0.5 square meter (775 square inches). The embryos of sharks and lungfishes have external gills like those of amphibians. When the oxygen supply is low, fishes snap at the surface for air to enrich their supply. Very sensitive trout die when the oxygen content declines to 1.5 cubic centimeters/liter; and the less sensitive carp do not perish until oxygen has dropped to 0.5 cubic centimeter/liter.

Blood Circulation. The heart in fishes lies behind the gill arches and in front of the pectoral girdle in a pericardium with a partition between it and the visceral cavity. The heart has one atrium and one ventricle separated by valves. See Fig. 4. In sharks, rays, and sturgeons, a muscular element (the *conus ateriosus*) lies between the chambers and the aorta, the inside of which has from two to eight half-moon-shaped valves. Only a remnant of this structure is present in teleost fishes. In its place, there is an enlargement of the aortic branch with a *bulbus ateriosus*, which prevents a backflow of blood pumped through the heart. Lungfishes have an atrium which is divided into two parts by a partition, thus separating oxygen-poor (*venous*) blood (from the liver) from oxygen-rich (*arterial*) blood out of the lung. The heart pumps the blood through the *aorta ascendens* to the gills, and blood replenished with oxygen passes from the gills to the *aorta descendens*, which supplies all the organs with blood. Venous blood circulates back to the heart from the *sinus venosus*.

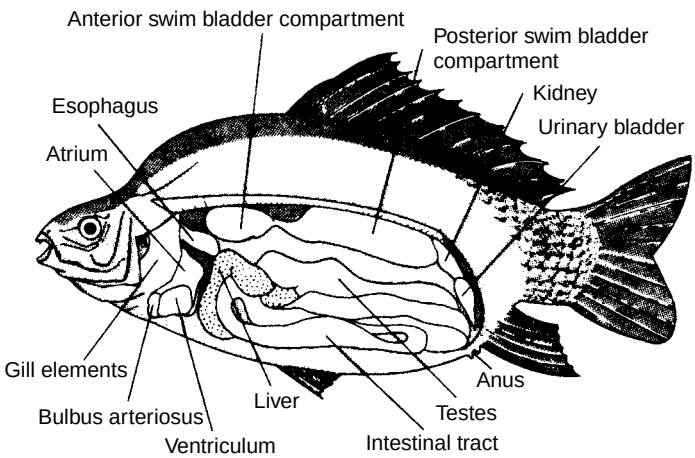

Fig. 4. Internal organs of a representative fish. Carp (*Cypriniformes*.)

Fishes also have a lymphatic system that empties into the veins. A few glands that secrete internally empty their contents into the blood circulating through them. Among these, the thyroid is responsible for metabolism; the thymus for growth; the pancreas for producing digestive juices and control of blood sugar levels; the pituitary gland for fat and carbohydrate metabolism, propagation of coloration material, blood pressure, stimulation of the smooth muscles, and other functions. Other significant organs include the gonads, which influence sexual activity; the adrenals, which influence breathing rate as well as heartbeat; the sympathetic nervous system and vascular muscles.

Digestive Tract. In contrast to the lampreys with their round mouths and rasping tongues, fishes have a jawed mouth adapted for swallowing food. It leads to the pharynx and from there into the muscular esophagus. The esophagus leads into the stomach without any striking transition, and from there the small intestine extends all the way to the anus. A short large intestine completes the system and has an external opening. The teeth are highly variable in shape and number; they correspond to the placoid scales of cartilaginous fishes. They lie on the jaw edges, on the palate and pharynx bones, and sometimes on the hyoid bone and gill arches. In predatory fishes, they are pointed or conical, in other fishes wide and smooth or chisel-shaped. Species that feed on minute crustaceans (for example pipefishes) are toothless. Plankton feeders (e.g., salmon) have elongated thorny processes on the gill arches, which serve as sieves and retain the plankton. Carp have teeth only on the lower pharyngeal bone.

In herring and perch, the esophagus leads to an enlarged muscular stomach with a blind end, which acts as a gizzard. The gut is winding and has a mucous membrane inside arranged longitudinally. In sharks, sturgeons, and lungfishes, the gut convolution system merges into a single screw-shaped spiral fold, which increases the surface. There are no salivary glands. The liver is large and rich in fat. Sturgeons and many teleost fishes have several hundred short glandular blind tubes in the beginning of the mid-intestine. It is assumed that they increase the absorptive area. The anus is always located ventrally, but in genera *Gymnotus* and *Fierasfer* in the throat region. Sharks and lungfishes have cloacae; thus the intestine culminates with the urinary and genital tracts in a hollow cavity which leads to the outside through the anus.

Genital Organs. With the exception of a few hermaphroditic forms, most species are bisexual and have paired genital organs, which lie on both sides of the vertebral column in the visceral cavity. In a few cases, they are united to form a single sack. In sharks, lungfishes, and ganoid fishes, the Müllerian duct, a part of the original ureter, takes up eggs released from the ovary and passes them to the outside. A part of the mesonephron serves as the spermatic duct. In salmon and eels, the eggs pass into the visceral cavity through a break in the ovarian wall and are passed out through paired genital pores behind the anus. In most teleost fishes, the testes and ovaries connect immediately with the spermatic ducts and oviducts, respectively, which together with the urinal tract terminate at the genital papilla behind the anus.

Male sharks and rays as well as a few teleost fishes have copulatory organs in the form of long cartilaginous appendages on the ventral fins. Other fishes giving birth to live young (e.g., toothed carps) have copulatory organs formed from the anal fin. In the European bitterling female, the genital pore is extended to form a 2-inch (5-centimeter) long egg-laying tube during spawning.

Fish hobbyists do not generally use the sex organs — or primarily sexual characteristics — to recognize and differentiate the sexes, but instead rely on other derived differences between males and females, the secondary sexual characteristics. These include color differences or spawning colors of males, their spawning eruptions, and the increased size of particular fins during spawning. Occasionally, the sexes are distinctively different; for example, in the deep-sea fish genus *Ceratias*, the dwarf-sized males hang firmly to the females with their mouths, parasitize the females for nutrition and, in essence, are only sperm-creating creatures for the females. In black bass (*Centropristis*), a sexual transformation exists; females which have already undergone a breeding period become transformed to males. Parthenogenesis (development of young without fertilization) has been confirmed in the carp *Carassius auratus gibelio*.

Spawning. See separate entry in this volume on **Spawning**.

Feeding Characteristics. There is much evidence among the fishes of adaptation to means for gaining food and for handling it, once contacted. Many tools of attack have been developed. The sawfish has an extremely elongated snout, which is equipped with from 15 to 30 pairs of teeth to form a crude, but effective saw that the fish flails through the water, randomly maiming prospective morsels, returning to eat the pieces at will. A paddlefish has an enormous mouth, swimming with it wide open. The greatly elongated paddle attached to the upper portion of the head is not generally accredited with assistance in food gathering, but when finally investigated it may well prove that the paddle has this major function. Some mormyrids have lower jaws shaped like trowels, which they use for "shoveling" when scrounging muddy bottoms for insects and worms. Some fishes, such as the suckermouth catfish, are equipped with powerful sucking mechanisms for obtaining food. The electrogenic fishes, such as the electric catfish or electric eel, use their voltage-generating batteries both for detecting the presence of food and for defense. The interesting angler fish dangles a lure hanging from a "pole" in front of its mouth to attract small fishes which can quickly be gulped or sucked into the mouth. The archerfish propels pellets of water to hit likely prospective food items. Experiments have shown that the fish can hit a target with reasonable accuracy up to a distance of three or more feet (0.9+ meter).

Lateral Line. Known as the *linea lateralis*, the lateral line detects water pressure which acts on the swimming or motionless fish. This extends from the head to the tail on both sides of the body and maintains contact with the water via its numerous pores. If the fish approaches an obstacle or a larger fish, the lateral line senses the resulting pressure change, and furthermore determines the direction and strength of currents so that those fishes that, when spawning, must swim up current, can find even the smallest streams. At night, or in muddy water, the lateral line protects the fish from bumping into objects, since these objects reflect the waves generated by the fish. Involuntary reflex equilibrium movements stimulated by the inner ear and lateral line are carried out by the paired fins and lateral musculature of the trunk and enable the fish to maintain its normal position in the water.

Velocity. The velocity of fishes is highly variable. Some carp can swim 7.5 miles (12 kilometers) per hour; barbels reach 11.2 miles (18 kilometers) per hour; while pike attain 15.5 miles (25 kilometers), and

trout 21.7 miles (35 kilometers) per hour. Among marine fishes, tuna can swim about 13.7 miles (22 kilometers) per hour; sharks about 22.4 miles (36 kilometers) per hour; and swordfish up to 60 miles (90 kilometers) per hour.

Coloration. Fish coloration stems from chromatophores located along the border of the epidermis and the subcutis, and also from fatty dyes (red, orange, or yellow lipophores, which are carotenoids dissolved in fat). Color cells are under central nervous system control and when stimulated either cause color to appear or eliminate coloration already present. Changing coloration enables fishes to adapt quickly to their surroundings. Skates and flatfishes not only assume the color of the floor, but also the sandy or gravel texture by forming imitative spots on the upper surface of their bodies. See also **Flatfishes**. Other environmental factors, such as higher water temperature, oxygen deficiency, or behavioral factors like fear, aggression, and similar stimuli can cause color changes. An aggressive male stickleback can change its appearance at short intervals. A color change appears in many fishes (such as salmon) when they are ready for spawning. The male develops a very colorful display pattern, and the epidermis develops wart-like spawning eruptions — as in salmon, chondrostomes (*Chondrostoma*), and European roaches.

The epidermis gives off a silvery mass consisting of fragments of decomposing material of the protein guanine. This forms an effective protective coloration, because a predator fish on the bottom sees a prey fish swimming above only as part of the glittering water surface. Bottom dwellers and deep-sea fishes generally are dark-colored. Coloration is lacking entirely in blind cavefishes, and the most colorful species are those of tropical inland waters and lakes.

Luminosity. Some sharks, e.g., the spiny dogfishes (*Squalidae*), emit a greenish phosphorescent light created by small light organs which lie throughout the skin. The deep-sea scaly dragonfishes (*Stomiatoidei*) have light organs consisting of a convex or concave lens which rests in one of the dermal vesicles of the epidermis. The walls of this vesicle are formed by glandular cells, which form the luminous material. If the walls contain black pigment, they act like the concave reflector of a dark lantern. In other cases, the outer skin layer lies over the upper surface of the lens and has about the same effect as the shutter of a camera. The luminous organs are arranged in two rows on both sides of the body. In addition, there are luminous organs on the head and jaws, and beneath or just behind the eyes.

Fishes of genus *Anomalops* from the Indian Ocean have a large luminous organ beneath the eye which sits on a movable flap which can be turned inward and fits in a cavity under the eyes. Lanternfishes (*Myctophidae*) have luminous organs on their stomachs and fins which have a jewel-like glitter. The *Galantheathauma*, caught in 1962 by the Galathea Expedition, has a light organ inside its mouth on the foregum; any prey attracted by the light has merely to swim inside the mouth, which then closes. The toadfish *Porichthys* from California coastal waters has about 340 light organs on head and body. These bright white spots consist of lens, gland, reflector and dye layer and they are so bright that a newspaper can be read 10 inches (25 centimeters) from them with no other light source present. The light comes from luminous bacteria or from the chemical reaction in mucus secreted by the gland cells. See also **Anglerfishes**. Lighting serves many functions to fishes so equipped, including species recognition.

Schooling. A school is a group in which all individuals are headed in the same direction, are uniformly spaced in close rank, and are swimming at the same speed. This is a general, but not exclusive definition. A logical analysis of schooling behavior begins with the recognition that regimented behavior of individuals is essential to the unity of the school. The school remains a unit when the individuals are coordinated with one another, either collectively or unilaterally. Schooling behavior is not defined by the spatial orientation of individuals, but rather, the spatial orientation is defined by the occupation of the school; that is, whether it is stationary, feeding, or swimming off to some other locality. The independent variable is the intact unit and the variables of spacing, direction, and speed of individuals are dependent upon the occupation of the school.

Schooling behavior changes with age in some species. The young of the black bullhead (*Cottus gobio*), for example, form dense stationary schools with disoriented individuals in contact with one another, or moving schools of regularly spaced individuals. The intensity of schooling declines in older fish. In most species, the schooling response persists once it has developed among the juveniles. Juveniles rarely coexist in schools of larger fish, because they occupy exclusive habitats as, for example, the occupancy of shallow marginal waters by juvenile minnows or suckers, or the surface as opposed to depths by juvenile North Sea herring. In a dynamic sense, juveniles may be segregated because they cannot swim fast enough to stay with the larger fish, or because the fish establish dominance hierarchies and drive away others of different sizes. The segregation of schools according to size, and thus the age, of the fish, continues throughout the life span of the species. The age-exclusiveness of schools is most clearly defined in the first few years, when the age-length correlations are most distinct. This does not mean that the individuals within a school are of uniform length — they may vary by a factor of 2 or 3, depending on the mean. However, the mean length between schools differs significantly.

Some changes in schooling behavior are related with either short-term or long-term environmental variations, which are generally interpreted as sources of physiological stress. In the laboratory, increased stress, as caused by low temperatures, elevated carbon dioxide or chlorine content, or stimulants, such as strychnine or caffeine, may intensify the schooling response. Other intensifying causes are noises, sudden motion of objects, a strange object in the aquarium, or novel surroundings, which might be created merely by transferring the fish to a different aquarium. The Schreckstoff (fright substance) released by injury to the skin in certain fish, notably the freshwater ostariophysids, initiates a flight reaction that is rapidly transmitted as a visual sign and causes fish to form tight schools or to seek cover, depending on species. In the absence of Schreckstoff, a flight reaction is transmitted by visual means. A reduction in stress as might be represented by the monotony of conditions in the laboratory aquarium induces a relaxation in the regimentation of schools, to different degrees in different species, and the response may vary with the size of the aquarium.

In nature, schools are generally spindle-shaped, and if only two or three fish are involved, they usually resort to following one another. Compact pods or balls are frequently seen, and a common formation is the mill, in which the school rotates in one spot like a large wheel on a fixed axis. The significance of such formations is generally unknown, although some are thought to represent reproductive or protective behavior and others may represent a response to physical conditions. Many species become quiescent during the cold seasons, and some, such as the bullheads, are known to form dense congregations in specific areas, suggestive of denning among snakes. The overall form of a school may depend upon the number of individuals comprising it. Changes in the structure of a large school of black mullet (*Mugiloidei*) were correlated, along the axis of progression, with metabolic reduction of dissolved oxygen. This is an interesting example of an aquatic group establishing its own limiting conditions.

There is no dichotomy between schooling and nonschooling fishes. The two categories lie at opposite ends of a continuous scale expressing time devoted to schooling behavior. Occupying the top of the scale would be species of whitefish, herring, sardine, mackerel, and tuna, and, at the bottom, solitary predators, such as trout, pike, and barracuda, or demersal or seclusive species, such as the sculpins and flatfishes.

A more detailed analysis of schooling motivation and behavior is beyond the scope of this volume. Much research has been done, and much remains. Further reference to the John (1969) and the Burgess-Shaw (1979) sources listed at the end of this entry is suggested. In addition to knowledge of schooling for strictly scientific purposes, this information also is very useful in improving the catches of various fisheries throughout the world.

Depth Preferences of Various Species. There is a considerable bank of scientific knowledge as regards the depth preferences of various orders and suborders of the fishes and, in fact, broad classifications have been made. There is less knowledge as regards those factors which bring about a differentiation of habitat in terms of depth; on how some species can vertically migrate considerable distances, while others remain constantly in certain depth zones. Some research into this topic has been conducted by the Scripps Institution of Oceanography (La Jolla, California) as well as other similar institutions. Some interesting findings are reported in the Siebenaller-Somero (1978) reference listed at end of this entry.

As pointed out by Bruchhausen et al. (1979), until quite recently there was much speculation as regards the existence of life in the relatively deep culdesacs beneath the large Antarctic ice shelves. Earlier evidence was confined to various specimens collected through natural cracks in the shelf ice; or fishes collected near the leading edge of the shelf. In 1978, a research group lowered baited traps and a camera through the Ross Ice Shelf, Antarctica, to a depth of some 1960 feet (597 meters) below sea level. This experiment revealed the presence of fish, many amphipods,

and at least one isopod. Details of this experiment are reported in Science, 203, 449–450 (1979).

Other Articles on Fishes. There are well over 100 separate articles on the various fishes throughout this encyclopedia. Consult Tables 1 and 2 of this article and refer to alphabetical index.

FISH FARMING. See **Aquaculture**.

FISH FLY *(Insecta, Neuroptera).* Species related to the corydalus. The larvae are aquatic and the adults are found near water. The insect is related to the alder fly. The larvae are sometimes used as fish bait.

FISH LOUSE *(Crustacea, Copepoda).* Minute marine and fresh-water animals parasitic on fishes.

FISH MEALS, OILS, AND PROTEIN CONCENTRATES. For many years, various species of fish, such as menhaden, tuna, groundfish, herring, sardine (at one time prior to recent periods of scarcity), and miscellaneous so-called industrial fish (monkfish, sculpin, sea robin, squirrel hake, shark, and ray) have been used as a source of nutritional meals and oils for use in feeding livestock, including poultry. When the concept of high-energy diets for livestock became popular in North America in the early 1950s, the feed industry became increasingly aware of various alternative sources in the formulation of balanced feeds. During interim years, the consumption of fish source materials has been essentially one of economics, balancing the costs of fish meals against those of other sources. The base cost of fish has risen largely because of increased labor and overhead costs and thus the use of fish sources tends to cycle with the economy.

Menhaden is the most important species for fish meal. Although tuna are not caught for the primary purpose of reduction, enormous numbers of them are canned and considerable wastes result from processing. The material thus becomes a raw material for reduction. Similarly, the wastes from various groundfish (alewife, salmon, haddock, ocean perch, whiting, cod, pollock) are used. The herring caught in New England waters is mainly used for canning, whereas the Alaska herring is reduced to meal. Industrial fish, previously mentioned, are mainly used for canned or otherwise preserved pet foods, but some tonnage is used for reduction. Sardines, no longer in generous supply, are principally canned, but wastes are sold for reduction.

In the United States, two principal methods of reduction are used: (1) Wet rendering, in which the oil is removed before the fish material is dried; and (2) dry rendering in which the oil is removed after drying. Wet rendering is most commonly used and is particularly well adapted to the rapid production of meal and oil from oily fish. In addition to the meal and oil produced, condensed solubles may also result from this method of processing. Dry rendering is well adapted to production on a small scale from fishery materials of low oil content, such as fillet waste from haddock and cod. Continuous dry reduction is also used with shrimp and crab scrap.

Wet Rendering. The principal steps of the wet rendering process are: (1) cooking, wherein the oil and water in the fish can be separated from the solid protein easily and economically in subsequent pressing operations. Overcooking and undercooking the fish results in an unsatisfactory product from the pressing operation, and thus cooking must be carefully temperature and pressure controlled. (2) Pressing (frequent screw-type press) squeezes both oil and water from the fish so that the resulting materials have a low oil content and are thus economical to dry. The product is called presscake. (3) Centrifuging is used instead of the formerly used settling tanks for recovery of the oil from the liquid portion. Two centrifuges are usually used — first a sludger, which handles liquor containing oil, water, and some suspended solids; then fresh, hot water is added to the emulsion for processing in a second centrifuge, known as the oil purifier, where the last traces of solids and water are removed. The solubles are stored and sold separately or a portion of them may be added back to the presscake, the resultant product, after drying, being called full meal in contrast to regular meal, which has no added solubles. (4) Drying in direct-heat dryers, steamtube dryers, or air-lift dryers is required to reduce the moisture content of meal down to about 9% to prevent spoilage and to make the product easier to handle and more economical to ship. (5) Deodorizing of the moisture-laden gases resulting from the removal of the fine meal particles is required because of objectionable odors present. Generally, the odor components of the gases must be removed before they may be discharged into the atmosphere. (6) The dried product, called scrap or unground fish meal must be cured. In general, fish oils are highly reactive, being characterized by a high degree of unsaturation, permitting easy combination of the oil with oxygen of the air, releasing considerable heat. This can result in charring and fire. To prevent this, some operators add antioxidants, usually to the dried scrap, but occasionally to the presscake before it is dried.

Dry Rendering. Although many variations in this method exist, the fishery material usually is loaded into a large, steam-jacketed, cylindrical drier. Inside the drier is a rotating scraper, which brings all material into quick contact with the hot inside wall, yet prevents the material from sticking. The drying is done either under vacuum or at atmospheric pressure. The oil is separated from the dried scrap by batch pressing in hydraulic presses. No product other than oil is recovered from this operation. After the oil has been expelled, the remaining solid material is ground into meal, called whole meal, or left unground as cake.

Fish Protein Concentrate. Sometimes referred to as FPC, this material has been defined as a stable product suitable for human consumption, prepared from whole fish or other aquatic animals or parts thereof. Protein concentration is increased by the removal of water and, in certain cases, of oil, bones, and other materials. The traditionally dried or otherwise processed fish meals do not fall within this definition. Many millions of dollars have been invested in research and pilot plants directed toward the production of fish protein concentrates during the past few decades. The objective has been the development of an effective protein source, particularly for the less affluent countries.

The use of minced fish as a basis for food products, such as *kamoboko*, a traditional fish paste, is a practice of long standing in Japan. Modern methods have been applied to this ancient art, and a major industry has arisen in Japan during the past few decades, producing a varied array of food products from minced fish.

Fish Protein Derivatives. Basically, these derivatives are prepared by reacting the myofibrillar protein with the acid anhydride under slightly alkaline conditions. The reacted proteins are then precipitated from solution with hydrochloric acid and extracted with hot azeotropic isopropanol to remove residual lipids. The acetylated proteins are then neutralized with sodium hydroxide to solubilize the derivatives, after which they are dried.

FISSION (Biology). A process of reproduction by the subdivision of the parent body into two or more approximately equal parts, which become independent individuals.

Fission is a common form of reproduction in the one-celled animals. Division of the cell into two parts, known as binary fission, is accomplished by mitosis. In very simple species, such as *Amoeba*, reproduction is no more than cell division. In species with constant body form, each half of the cell differs from the other and reproduction is not complete until it has undergone a reorganization with the development of all structures characteristic of its kind. Some protozoans, notably parasitic species, go through a process of subdivision into a number of parts simultaneously. This process is multiple fission or sporulation. Fissions occurs in multicellular animals of simple structure, including polyps and flatworms, by a gradual reorganization accompanied by the constriction and breaking of the body. Bacteria, as well as a number of the one-celled algae, also reproduce by fission.

FISSION REACTOR. See **Nuclear Power Technology**.

FISSION (Nuclear). See **Nuclear Fission**.

FISSURE IN ANO. A break or crack in the skin just internal to the margin of the anus. It is an exceedingly common condition, one that usually complicates hemorrhoids and causes excruciating pain. The crack becomes infected, is raw and tender. Simple early cases can be treated locally with success. Many causes cannot be cured without surgery.

FISTULA. An abnormal channel or communication leading from a body organ. (1) Anal fistula may result from infection of the anus and is usually the result of infective invasion of the numerous tiny glands or crypts, which abound in the tissues adjacent to the anus. In addition to the production of a fissure, hemorrhoid, or abscess, a fistula may be created. This happens if the infection spreads through the wall of the anus, causing an abscess in the tissues around the anus. This abscess may burst through the skin around the anus or back into the rectum. In either case, the abscess cavity has two openings—the original site of entry of infection and the point where it burst through. Unless treated, a chronic discharging fistula may be formed. General treatment is to remove both the gland in which the infection originated and the infected tract once the infection is under control.

(2) Bladder fistula is described under **Kidney and Urinary Tract**.

(3) Vascular fistulas are abnormal communications between vessels and defects in the septa of the heart. These cause shunts in circulation, causing large amounts of blood to be returned to one or both ventricles. In this situation, the output of one or both ventricles is increased in proportion to the size of the shunt. Specifically named vascular fistulas are: *Arteriovenous fistula* (both ventricles); *patent ductus arteriosus* (left ventricle); *atrial septal defect* (right ventricle); and *ventricular septal defect* (both ventricles).

FITCH. See **Mustelines**.

FITTING REACTION. The formation of aromatic hydrocarbons from aryl or aryl and alkyl bromides by the use of sodium, e.g., bromobenzene plus ethyl bromide plus sodium forms ethylbenzene plus sodium bromide, $C_6H_5Br + C_2H_5Br + 2Na \rightarrow C_6H_5 \cdot C_2H_5 + 2NaBr$.

FIXED BED. In processing terminology, a fixed-bed installation (usually a reactor) requires that materials in the solid phase that are to be reacted with gases and vapors remain in a fixed location. In other words, the flow in such equipment is that of the materials in the gaseous or vapor phase. The solid materials require careful preparation to permit a maximum of surface to be exposed to the gases that pass through them and to avoid the occurrence of channels, through which the gases would pass without contacting the bulk of the solids. Beds of this type are often used in connection with various catalytic operations and are used, for example, in the production of benzene, in catalytic reforming, hydrocracking, hydrotreating, vinyl chloride monomer production, and in ion-exchange operations. A later reaction development, but also one that is several decades old, is the fluid-bed reactor, in which the solids to be reacted are essentially "fluidized" and intermix with other solids or with gases in a rapidly moving turbulent stream–in contrast with the solids remaining in a fixed bed. Whether or not a fixed bed is used instead of a fluidized bed is determined by numerous factors, notably time and cost. Fixed-bed reactors tend to be simpler and less costly, but often require cyclic operation because of the need to replenish the solids (catalysts, etc.). Thus to achieve continuous production, two or more beds are required (one on stream; the other regenerating). See also **Fluidization**.

FIXED OILS. These are fats, compounds of glycerin and various complex fatty acids. Fixed oils are often called the nonvolatile oils, in distinction to the essential or volatile oils, which are readily vaporized by heat. It is characteristic of the fixed oils to leave a spot when dropped on paper. Many of them remain liquid at common room temperatures, others are solid at such temperatures. Solid forms are usually called fats, a purely arbitrary distinction since slight changes in temperature will cause many of them to change from liquid to solid or vice versa.

Fixed oils, especially those of economic importance, are largely obtained from the seeds of plants. They have a high energy value, so form a valuable food if they prove palatable.

Various methods are employed to obtain the oil from the vegetable tissues. Quite commonly, the seeds containing the oil are subjected to great pressures in hydraulic presses. This may be done without heating, but is frequently facilitated by heating the seeds, the oil being then hot-pressed instead of cold-pressed. More recently, the screw press has come into use. This press has a rotating screw, which presses the ground seeds under very high pressure through a cage-like cylinder. The oil is squeezed through openings in the cylinder walls, while the seed meal is discharged through an opening in the end of the cylinder. This procedure is advantageous in that it is continuous, and the machine need not be stopped for loading. A third method of obtaining the oil is by means of solvents. Following expression of the oil from the plant tissues, various methods of refining, decolorizing and deodorizing are employed.

Fixed oils are usually classified into three groups, drying, semidrying, and nondrying oils. Often a fourth group is made of those which are usually seen in solid form, the vegetable fats, although they differ but little otherwise from the other groups.

Drying oils are those which on exposure to air form a tough elastic film. Linseed oil from flax seeds is one of the most important and is largely used in making paints and varnishes. Tung oil, obtained from the fruits of *Aleurites fordii*, is a valuable oil much used in the manufacture of waterproof varnishes and quick-drying enamels. The tree, a native of China and Japan, has been introduced into Florida. Other drying oils are nut oil, from walnut seeds, poppy seed oil, hemp seed oil, and sunflower oil, the latter largely a product of the former U.S.S.R.

Nondrying oils are those which remain permanently greasy or sticky, becoming rancid after a time. Among these oils the most important are olive oil, castor oil from the seeds of the castor bean plant, rape seed oil, peanut oil, almond oil, used medicinally, and tea seed oil.

Semidrying oils are intermediate in nature. The principal semidrying oils are cotton-seed oil, Soyabean oil, corn or maize oil and sesame oil. The latter is obtained from the seeds of *Sesamun indicum*, a member of the

Pedaliaceae, cultivated in India, China and Japan, where the oil is much used as a food oil and for cooking.

Nondrying oils that are ordinarily solid are palm and palm-kernel oil, coconut oil, and cocoa butter. Another interesting oil of this group is macassar oil, obtained from the seeds of *Schleichera trijuga*, one of the *Sapindaceae*, occurring in tropical Asia. The oil was formerly much used as a potential "hair restorer," necessitating the use of removable covers, or antimacassars, on the backs of upholstered chairs. The same tree also yields a useful timber.

FIXED POINT ARITHMETIC (Computer System). A method of storing numeric data in a computer such that the data are all stored in integer form (or all in fractional form) and the user postulates a radix point between a certain pair of digits. Consider a computer whose basic arithmetic is in decimal and in which each computer word consists of seven decimal digits in integer form. If it is desired to add 2.796512 to 4.873214, the data are stored in the computer as 2796512 and 4873214, the sum of which is 7669726. It is recalled that a decimal point between digits 1 and 2 has been postulated. The result, therefore, represents 7.669726. Input and output conversion routines often are provided for convenience. These routines can add or delete the radix point in the external representation and align the data as required internally.

In as much as the arithmetic operations usually are the basic arithmetic operations of the computer, fixed-point operations are fast and thus preferred over floating-point operations. It is important, of course, that the magnitude of the numbers be much better known than for floating-point numbers, since the absolute magnitude is limited by word size and the availability of double-length operations. For many applications, fixed-point calculations are practical and do increase speed.

See also **Floating-Point Arithmetic**.

FIXED-POINT SYSTEM. See **Point**.

FIX (Navigation). The position of a ship as determined by the intersection of two or more lines of position. Since lines of position are determined in all of the observational types of navigation, pilotage, celestial, or radio, it is obvious that a fix may be defined as any position of a ship determined by observational means.

All observational methods are subject to unavoidable errors of observation; therefore, a line of position is not strictly a line, but is a band of constant width, as in the case of a line determined by celestial navigation, or of width that increases from the point of observation (e.g., in pilotage or radio navigation). Hence, a fix is not strictly a point, but is a polygon, whose area depends upon the accuracy of the observational material employed in determining the "line." With two lines of position, the area will be a quadrilateral, and the area will be a minimum when the lines are at right angles to each other. Three lines of position will seldom, in practice, intersect in a point, but will bound a triangle. The standard symbol for indicating the position of a fix on a geographic plot is a triangle with a dot at the center. This symbol is used no matter how many lines are employed in determining the position, the point being the point of intersection of two lines, or, when more than two lines are used, the center of the polygon.

When the observations for the lines of position can be taken simultaneously, a fix can be immediately determined for the instant at which the lines were observed. Simultaneity of observation is seldom possible, and the question of movement of the ship between observations must be carefully considered. It is safe to say that, if the ship does not move more than 2 miles (3.2 kilometers) between observations, the fix may be considered as the intersection of the lines as directly plotted, with the time of the fix recorded as the average of the times of observation.

If the ship has moved appreciably (more than 2 miles; 3.2 kilometers) between observations, the method of running fix must be employed. To obtain a running fix, the selected time of the fix is usually the time of observation of some one of the lines, and the other lines are advanced or retarded to that line by standard dead-reckoning methods. In certain cases, e.g., when a noon position is desired and the only observations available are one before noon and another after noon, both lines are moved, one forward and the other backward, to the desired time. Before considering a specific case, it should be remembered that, by definition, a line of position is a line on which a ship is situated. For the purpose of moving the line, any conveniently located position may be selected, advanced, or retarded by dead reckoning, and a line drawn parallel to the observed line through the DR point will be the advanced line. The use of parallel rulers is convenient, but not essential, for this purpose. If the line of position is appreciably curved, due to the fact that the center of the circle of position is relatively close to the observer, the position of the center must be found, advanced by dead reckoning, and a new circle drawn, using the radius of the original circle.

The following situation illustrates the method for obtaining the running fix of a line of position obtained by celestial navigation and by pilotage:

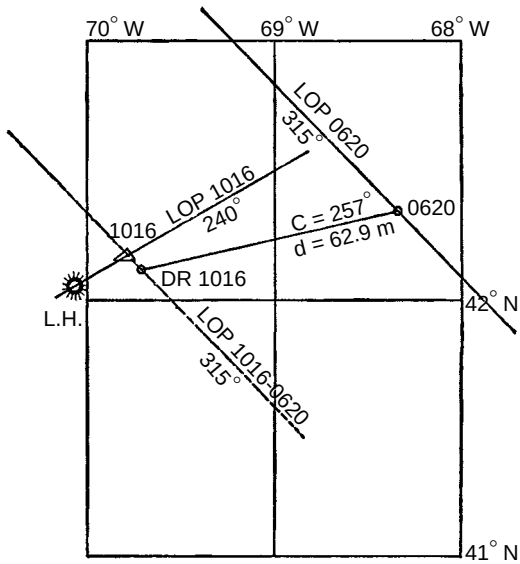

Fig. 1. Scale diagram on mercator plotting sheet.

At 0620, a ship is in L (latitude) = 42°20′.8 N & Lo (longitude) = 68°20′.1 W, and is proceeding at 16 knots on course 257°. At 0620, a line of position is obtained by celestial navigation, with the line running in the direction 135°–315°. At 1016, a lighthouse in L = N42°02′.4&Lo = 70°03′.7 W is sighted on bearing 240°. The 1016 position of the ship is desired.

In Fig. 1, the problem is plotted on a mercator plotting sheet, with all lines labeled in accordance with U.S. Navy procedure. Through the 0620 position, the line of position (LOP) is drawn in the 135–315°. The course line is drawn in direction 257°, and the 1016 DR position is plotted on this line 62.9 miles (101.2 kilometers) (the distance run at 16 knots between 0620 and 1016) from the 0620 position. Through this DR position, a line is drawn parallel to the 0620 LOP, thus giving the advanced line of position. Through the lighthouse, a line is drawn in the 240°–060° direction, and this is the 1016 LOP. The 1016 fix is determined to be at L = 42°09′.6 N & Lo = 69°46′.5 W. See also **Course**; **Dead Reckoning**; **Navigation**; and **Pilotage (or Piloting)**.

FIZEAU EXPERIMENT (Light). This experiment provided confirmation of the conclusion that the speed of light increases by an amount

$$v\left(1-\frac{1}{n^2}\right)$$

when moving through a medium, of refractive index n, which itself is moving with velocity v. A beam of light was divided into two parts which were sent in opposite directions through two tubes filled with flowing water, and interference fringes were observed as a function of the velocity of the water. The result is a consequence of special relativity theory.

FIZEAU, HIPPOLYTE (1819–1896). Fizeau was a French astronomer and a physicist. He began his career studying medicine then changed directions and pursued the physical sciences. He studied at the Paris Observatory under Arago. He also worked with Leon Foucault and took photographs of the surface of the sun. Also Fizeau and Foucault worked on predictions of the wave theory of light.

See also **Fizeau Experiment (Light)**.

J. M. I.

FJORD. (Sometimes spelled fiord, fiard.) A deep-water inlet, usually surrounded by mountains; specifically a submerged U-shaped valley carved out by glacial action. The fjord is characteristic of the coastal regions of Norway, western Scotland and Ireland, Greenland, Labrador, Alaska, British Columbia, southern Chile, the Antarctic peninsula, southwest New Zealand, and other high-latitude oceanic islands (Iceland, Spitzbergen, Kerguelen, etc.).

FLAC (Free Lossless Audio Codec). See **Data Compression**.

FLAGELLATES. This is a large group of organisms, of particular interest because of the position they occupy in the organic world. There are both plant (described here) and animal (*Mastigophora*) flagellates.

They are usually one-celled organisms, of extremely complex structure. Many of them have no cell wall of cellulose, lack the green pigment, chlorophyll, and are definitely animals. Others possess a distinct wall of cellulose and have chloroplasts, and are set off as plants. The separation of these two groups is not sharp, however, and some of the plant members are obviously very closely related to very similar animal forms. Therefore it is impossible to stress the differences which are used as a basis for classification. Characteristic of the flagellates is the flagellum, a long lash-like extension from the protoplast. The vibrations of the flagellum propel the organism through the water, in which they usually occur.

See also **Dinoflagellata**.

FLAGELLUM. A long slender hair-like projection from a cell; it may be used for a variety of purposes. In many plant and animal sperms it serves as a means of locomotion. It also serves this purpose in the flagellated bacteria and in the flagellated protozoans. In the sponges, the flagella of many of the cells lining the pores keep a current of water passing into the body. A flagellum differs from a cilium primarily in length and number. Cilia are much shorter and usually are present in greater quantity.

The electron microscope shows that there is a group of mitochondria at the base of each flagellum. The flagellum is made of an outer membrane, beneath which is a cable of nine protein fibers in a circle and with two fibers in the center.

FLAME CUTTING. Cutting of ferrous metals by oxidation, using a stream of oxygen from a blowpipe or torch. The metal is preheated to a bright red, approximately 1500 °F (816 °C) by fuel gas jets in the cutting torch. The stream of oxygen is then applied through a central jet. Once oxidation of iron to Fe_3O_4 begins, the heat of the reaction plays a large part in the continuation of the process. Approximately 30% of the molten metal is removed without actual oxidation by the mechanical washing action of the stream of gas and burnt metal. The preheating gases are oxy-acetylene, hydrogen, natural gas, city gas, etc.

The oxygen lance is a form of flame cutting in which oxygen, supplied through an iron pipe, is the only agent used. It is used for heavy-duty cutting.

Very heavy sections may be cut with the blowtorch. Close dimensional tolerances can be maintained, using machine operated torches, thus flame cutting has become a production tool as well as a means of salvaging scrap. Underwater flame cutting is possible at depths of 135 feet (40.5 meters) or more using special practice.

FLAME HARDENING. Surface hardening of steel or cast iron by heating a thin surface layer to the hardening temperature with an oxy-acetylene flame, followed by rapid cooling. Depending on the nature of the part to be hardened, either the torch system or the work itself may be moved. Cylindrical parts are rotated before a stationary flame. An air jet or liquid spray following the torch is used to quench-harden the surface. The relatively cool metal in the interior hastens cooling of the surface by conduction. The depth of flame hardening may be less than $\frac{1}{16}$ inch to about $\frac{1}{4}$ inch (1.6–6 millimeters), depending on the thickness of the section and the service requirements. Distortion is generally less than in parts hardened by general heating and quenching.

Since no hardening agent such as carbon or nitrogen is added to the surface of the steel by this process, only steels having sufficient carbon to harden readily upon quenching are used for flame hardening. The most desirable range is 0.35–0.70% carbon. The hardening treatment is followed by a low-temperature tempering treatment to relieve quenching strains. Typical applications of flame hardening are gear teeth, cams, bearing surfaces, rail ends, crankshafts, and many other machine parts and tools.

FLAME PHOTOMETRY AND SPECTROMETRY. The basic principle of flame emission spectrometry rests on the fact that salts of metals, when introduced under carefully controlled conditions into a suitable flame, are vaporized and excited to emit radiations that are characteristic for each element. Correlation of the emission intensity with the concentration of that element forms the basis of quantitative evaluation.

The determinations of sodium and potassium constitute the majority of published applications. However, the flame is a suitable emission source for at least 45 elements, which may be grouped as follows:

1. *Elements determined*: aluminum, barium, boron, calcium, cesium, chromium, copper, iron, lead, lithium, magnesium, manganese, potassium, rubidium, sodium, strontium.

2. *Elements determined but sometimes overlooked*: antimony, arsenic, bismuth, cadmium, cobalt, gallium, indium, lanthanum, nickel, palladium, rare earths (except cerium), rhodium, ruthenium, scandium, silver, tellurium, thallium, tin, and yttrium.

3. *Elements with distinctive but less sensitive flame spectra*: beryllium, germanium, gold, mercury, molybdenum, niobium, rhenium, selenium, silicon, titanium, tungsten.

4. *Elements determined by indirect means*: bromine, chlorine, fluorine, iodine (although bromine, chlorine and fluorine can be determined by their metallic halide spectra), phosphorus, and silicon.

Materials in which these elements are determined by flame spectrometry include water, glasses, cement, soils, fertilizers, plant materials, biological fluids and tissues, petroleum products and metallurgical products.

The *flame spectrometer*, used in emission spectrometry, consists of: (1) the pressure regulators and flow meters for the fuel gases; (2) the atomizing device; (3) the flame source; (4) the optical system; (5) appropriate photosensitive detectors; and (6) the electrical circuit for measuring or recording the intensity of the radiation. Depending upon the use intended, the instrument may be a relatively simple assemblage of interference filters and a photodetector, i.e., a flame photometer, or it may be an elaborate prism or grating monochromator, i.e., a flame spectrometer such as the instrument illustrated in Fig. 1.

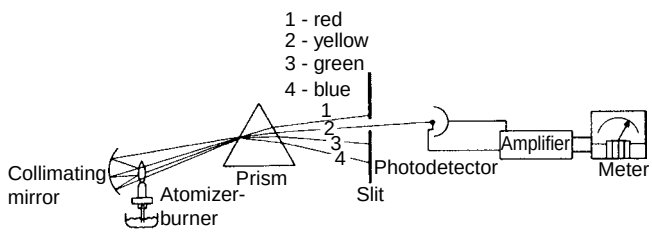

Fig. 1. Flame spectrometer.

Virtually all flame spectrometers rely on atomization to deliver a steady flow of solution to the flame. The solution is drawn through a capillary positioned either concentric with or at right angles to the annulus or capillary from which the aspirating gas (oxygen or air under pressure) enters. At the tip of the solution capillary, the liquid is sheared off and dispersed into droplets by the blast of oxygen or air.

The best isolation of radiant energy can be achieved with flame spectrometers that incorporate either a prism or grating monochromator, those with prisms having variable gauged entrance and exit slits. Both these spectrometers provide a continuous selection of wavelengths with resolving power sufficient to separate completely most of the easily excited emission lines, and afford freedom from scattered radiation sufficient to minimize interferences. Fused silica or quartz optical components are necessary to permit measurements in the ultraviolet portion of the spectrum below 350 nanometers. See also **Analysis (Chemical)**; **Atomic Spectroscopy**; **Photometers**; and **Spectro Instruments**.

FLAME RETARDANTS: ANTIMONY AND OTHER INORGANIC AGENTS. Flame retardancy can be imparted to plastics by incorporating elements such as bromine, chlorine, antimony, tin, molybdenum, phosphorus, aluminum, and magnesium, either during the manufacture or when the

plastics are compounded into some useful product. Phosphorus, bromine, and chlorine are usually incorporated as some organic compound. The other inorganic flame retardants are discussed herein.

Addition of approximately 40% of the halogen flame retardants are needed to obtain a reasonable degree of flame retardancy. This usually adversely affects the properties of the plastic. The efficiency of the halogens is enhanced by the addition of inorganic flame retardants, resulting in the overall reduction of flame-retardant additive package and minimizing the adverse effects of the retardants.

Hydrated metal oxides such as alumina hydrate are usually used alone because these are not synergistic with the halogens. They are useful in applications in which the halogens are excluded or low processing temperatures are used.

Antimony Compounds

Antimony Trioxide. [CAS: 1309-64-4] (commonly referred to as antimony oxide), Sb_2O_3 is used to impart flame retardancy to plastics. Although antimony trioxide is found in nature, it is too impure to be used. Flame-retardant grades of antimony oxides are manufactured from either antimony metal or the sulfide ore by oxidation in air at 600–800 °C. The particle size and chemical reactivity is determined by the processing conditions, enabling the production of several different grades. Antimony trioxide is from 99.0–99.9 wt % Sb_2O_3. The remainder consists of 0.4–0.01 wt % arsenic; 0.4–0.01, lead; 0.1–0.0001, iron; 0.005–0.0001, nickel; and 0.01–0.0001, sulfates. It is insoluble in water and the loss on drying at 110 °C is 0.1 wt % max.

Antimony trioxide has been used as a white pigment since ancient times. The pigmentation from antimony oxide in plastics can be controlled and adjusted by the judicious selection of a Sb_2O_3 grade having a specific particle size. The product with the smallest particle size and the narrowest particle-size range imparts the whitest color and highest opacity. Translucent plastics can be made by using low tint grades with relatively large particles.

Antimony Oxide as a Primary Flame Retardant. Antimony oxide behaves as a condensed-phase flame retardant in cellulosic materials. It can be applied by impregnating a fabric with a soluble antimony salt followed by a second treatment that precipitates antimony oxide in the fibers. When the treated fabric is exposed to a flame, the oxide reacts with the hydroxyl groups of the cellulose causing them to decompose endothermically. The decomposition products, water and char, cool the flame reactions while slowing the production and volatilization of flammable decomposition products. See also **Cellulose**; and **Flame Retardants: Textiles**.

Antimony Pentoxide. The second most widely used antimony synergist is antimony pentoxide [CAS: 1313-60-9], Sb_2O_5, produced by the oxidation of the trioxide using either a peroxide or nitric acid. Antimony pentoxide is available as a nonpigmenting colloidal suspension in either water or organic media or as an agglomerated powder. It is insoluble in water, but soluble in hot concentrated acids.

Submicrometer antimony pentoxide is primarily used to impart flame retardancy to fibers and fabrics. It can be added to the molten or dissolved polymer prior to forming the fiber. The antimony in this form can easily pass through the spinnerets without clogging the openings, whereas standard grades of antimony trioxide would rapidly clog the openings and necessitate frequent shutdowns for cleaning. The submicrometer antimony pentoxide is also more evenly dispersed in the fiber, resulting in better physical properties.

Powdered antimony pentoxide is used primarily in plastics. Stabilizers used to prevent the particles from growing are caustic, and can react with the halogen in the formulation. This can result in color formation and a lower flame-retarding efficiency of the system.

Sodium Antimonate. Sodium antimonate [CAS: 15593-75-6], Na_3SbO_4, another antimony synergist of commercial importance, has an antimony content of 61–63 wt % and a bulk density of 39.4–46.4 kg/m3. It is made by oxidizing antimony trioxide using sodium nitrate and caustic. It is a white powder and has a pH of around 9–11 when dissolved in water.

Sodium antimonate contains less antimony than either antimony trioxide or pentoxide and is thus less effective. However, its unique pH and low refractive index makes the antimonate the most desirable synergist for polymers that hydrolyze when processed with acidic additives or in polymers for which deep color tones are specified.

Toxicity. Antimony has been found not to be a carcinogen or to present any undue risk to the environment. However, because antimony compounds also contain minor amounts of arsenic which is a poison and a carcinogen, warning labels are placed on all packages of antimony trioxide.

Boron Compounds

Boron flame retardants are used in the United States to impart flame retardancy to plastics. See also **Boron**. The most widely used is zinc borate [CAS: 1332-07-6], prepared as an insoluble double salt from water-soluble zinc and boron compounds. Compounds having varying amounts of zinc, boron, and water of hydration are available. The ratio of these components affects the temperature at which the flame-inhibiting powers are activated, as well as the temperature at which they can be processed. Zinc borates can either be used alone or in combination with other halogen synergists, such as antimony oxide. In some instances zinc borate is also used with alumina trihydrate to form a glass-like substance that inhibits polymer degradation.

Barium Metaborate. Barium metaborate [CAS: 13701-59-2] is used both as a flame retarder and as an antifungicide for many flexible poly(vinyl chloride) applications.

Boric Acid and Sodium Borate. Boric acid [CAS: 10043-35-3] and sodium borate [CAS: 1303-96-4], also known as borax, have been used as flame retardants for cellulose since the 1800s. They are quick-fix, nondurable flame retardants. Each is applied by passing the fabric through a solution of the flame retardant. For batts, eg, cotton, a spray applicator is used. Excess solution is removed by passing the fabric through squeeze rollers. Usually an "add-on" of 20% is needed to obtain flame retardancy. However, because the flame retardants are water-soluble, they are removed after several washings or when used in high humidity atmospheres.

Boron functions as a flame retardant in both the condensed and vapor phases. Under flaming conditions boron and halogens form the corresponding trihalide. Because boron trihalides are effective Lewis acids, they promote cross-linking, minimizing decomposition of the polymer into volatile flammable gases. These trihalides are also volatile; thus they vaporize into the flame and release halogen which then functions as a flame inhibitor.

Boron also reacts with hydroxyl-containing polymers such as cellulose. When exposed to a flame the boron and hydroxyl groups form a glassy ester that coats the substrate and reduces polymer degradation. A similar type of action has been observed in the boron–alumina trihydrate system.

Alumina Trihydrate

Alumina trihydrate [CAS: 12252-70-9], $Al_2O_3{\cdot}3H_2O$, the most widely used flame retardant, used to inhibit the flammability of plastics processed at low temperatures. Alumina trihydrate is manufactured from either bauxite ore or recovered aluminum by either the Bayer or sinter processes. In the Bayer process, the bauxite ore is digested in a caustic solution, then filtered to remove silicate, titanate, and iron impurities. The alumina trihydrate is recovered from the filtered solution by precipitation. In the sinter process the aluminum is leached from the ore using a solution of soda and lime from which pure alumina trihydrate is recovered. See also **Aluminum**.

Alumina trihydrate is the least expensive and least effective of the flame retarders. It is only about one-fourth to one-half as effective as the halogens. Usually about 50–60% of alumina trihydrate is needed to obtain some acceptable degree of flame retardancy. It is also limited to plastics that are not processed higher than 220 °C.

Alumina trihydrate is also used as a secondary flame retardant and smoke suppressant for flexible poly(vinyl chloride) and polyolefin formulations in which antimony and a halogen are used. The addition of minor amounts of either zinc borate or phosphorus results in the formation of glasses which insulate the unburned polymer from the flame

Alumina trihydrate functions as a flame retardant in both the condensed and vapor phases. When activated, it decomposes endothermically, eliminating water. In the flame phase the water vapor forms an envelope around the flame, which tends to exclude air and dilute the flammable gases.

Other Inorganic Materials

Magnesium Hydroxide. Magnesium hydroxide [CAS: 1309-42-8] is another metal hydrate that decomposes endothermically, accompanied by the formation of water. It decomposes at 330 °C, which is 100 °C higher

than alumina trihydrate, and can therefore be used in polymers that are processed at higher temperatures. Magnesium hydroxide is white, has an average particle size of 1–10 μm, density of 2.36 g/mL, refractive index of 1.58, and Mohs' hardness of 2.00. Water loss on ignition is 31.8 wt %. Magnesium hydroxide contains 1.0 wt % $Ca(OH)_2$ and is made by Solem Industries and Morton Thiokol.

Molybdenum Oxides. Molybdenum was one of the first elements used to retard the flames of cellulosics. More recently it has been used to impart flame resistance and smoke suppression to plastics. Molybdic oxide [CAS: 1313-27-5] ammonium octamolybdate, and zinc molybdate [CAS: 13767-32-3] are the most widely used molybdenum flame retardants. These materials are recommended almost exclusively for poly(vinyl chloride), its alloys, and unsaturated polyesters.

Molybdenum is also a smoke suppressant for poly(vinyl chloride). It promotes the formation of cis- rather than the trans-polymeric decomposition products which are the precursors for smoke.

Tin. Tin has been used as a flame retardant for cellulose since the latter 1800s. Only since the 1970s has it been used as a synergist for halogen flame retarders in the same manner as antimony oxide. Anhydrous and hydrated zinc stannate [CAS: 12036-37-2] and stannic oxide [CAS: 18282-10-5] are the three most important tin flame retardants.

Applications

Poly(vinyl chloride). PVC is a hard, brittle polymer that is self-extinguishing. In order to make PVC useful and more pliable, plasticizers are added. More often than not the plasticizers are flammable and make the formulation less flame-resistant. The flame resistance of the poly(vinyl chloride) can be increased by the addition of an inorganic flame-retardant synergist, e.g., antimony oxide, mixed metal antimony synergists, zinc borate, molybdenum oxide, zinc stannates, and alumina trihydrate.

Zinc Borate. Zinc borate is also effective in enhancing the flame-inhibiting powers of chlorine. Although zinc borate increases flame resistance, it is not as effective as antimony oxide. However, zinc borate can be used in combination with antimony oxide to obtain equivalent and in some instances enhanced effects over what can be obtained using either of the two synergists alone.

Unsaturated Polyesters. There are two approaches used to provide flame retardancy to unsaturated polyesters. These materials can be made flame-resistant by incorporating halogen when made, or by adding some organic halogen compound when cured. In either case a synergist is needed.

Olefin Polymers. The flame resistance of polyethylene can be increased by the addition of either a halogen synergist system or hydrated fillers. Similar flame-retarder packages are used for polypropylene. See **Olefin Polymers**.

FLAME RETARDANTS: HALOGENATED. The total world market for flame-retardants is estimated to be more than 1.2 million metric tons valued at ~2.3 billion U.S. dollars. Approximately 36% of this revenue is based on bromine organic compounds and <10% on chlorinated organic compounds. The rest is made up of nonhalogenated organophosphate esters, halogenated organophosphate esters, alumina trihydrate, antimony oxides (antimony trioxide, pentoxide, sodium antimonate), boron compounds, magnesium hydroxide, ammonium polyphosphate and red phosphorus. Some of these inorganic compounds function as synergists rather than directly as flame-retardants, enhancing the effectiveness.

Flame retardant use is affected by regulation in two opposing ways. Government regulations (as well as voluntary trade standards and concern of litigation potential due to product failure) for flame retardancy of various products which dictate the use of flame retardants to meet given fire standards and government regulations governing what compounds are deemed to be safe for use in flame retardant applications and not have a negative effect on the environment or human health. Currently halogenated compounds are increasingly facing pressure from the second situation, which has seen a drive to expand the use of non-halogenated flame-retardants. Despite this, halogenated flame-retardants remain the most important group of flame-retardants in use today. Halogenated flame-retardants typically have high levels of either bromine or chlorine that coupled with their high efficiency allows these additives to be used at relatively low loadings. This in turn translates to a greater retention of the physical properties of the base polymer.

Halogenated flame-retardants fall into three general classes, additive, reactive and polymeric. Additives are blended into the polymer using common polymer processing equipment at the same time other ingredients such as synergists, stabilizers, pigments, and processing aids are added. This is typically true of polymeric flame-retardants as well but these materials also have the advantage of low blooming and less environmental concerns due to their polymeric nature. Reactive flame-retardants become part of the polymer by either reacting into the polymer backbone or grafting onto it.

The most important class of brominated flame retardants to date has been the polybrominated diphenyl oxides (diphenyl ethers) of which decabromodiphenyl oxide (Deca) is the largest volume product and whose primarily use is in HIPS (high-impact polystyrene). Octabromodiphenyl oxide was used primarily in ABS resins and pentabromodiphenyl oxide in flexible polyurethane foam. Both octa and penta diphenyl oxide have recently been banned in Europe. The sole U.S. production has ceased which will effectively remove these products from the market. Other highly brominated aromatic compounds have been developed as possible alternatives to Deca to address the concerns with diphenyl oxide based flame retardants and ethane-1,2-bis(pentabromophenyl) is one such example. Other types of brominated flame retardants have also come into wider use including tetrabromobisphenol-A, which is the largest volume, brominated flame retardant in use today. It can function as either an additive or a reactive flame retardant and is used as a raw material in the manufacture of other flame-retardants. Other newer flame retardants, which exemplify the move to polymeric flame retardants, include brominated polystyrenes, polybromostyrenes and brominated epoxy oligomers (BEOs).

The use of flame retardants came about because of concern over the flammability of synthetic polymers (plastics). A simple method of assessing the potential contribution of polymers to a fire is to examine the heats of combustion, which for common polymers vary by only about a factor of two. Heats of combustion correlate with the chemical nature of a polymer whether the polymer is synthetic or natural. Concern over flammability should arise via a proper risk assessment, which takes into account not only the flammability of the material, but also the environment in which it is used.

Fundamentals of Flammability

In order for a solid to burn it must be volatilized, because combustion is almost exclusively a gas-phase phenomenon. In the case of a polymer, this means that decomposition must occur. The decomposition begins in the solid phase and may continue in the liquid (melt) and gas phases. Decomposition produces low molecular weight chemical compounds that eventually enter the gas phase. Heat from combustion causes further decomposition and volatilization and, therefore, further combustion. Thus the burning of a solid is like a chain reaction. For a compound to function as a flame retardant it must interrupt this cycle in some way. There are several mechanistic descriptions by which flame retardants modify flammability:

inert gas dilution, thermal quenching, protective coatings, physical dilution, and chemical interaction.

Flammability Testing

One problem associated with discussing flame retardants is the lack of a clear, uniform definition of flammability. Hence, no clear, uniform definition of decreased flammability exists. The latest American Society for Testing and Materials (ASTM) compilation of fire tests lists over one hundred methods for assessing the flammability of materials.

Flame Retardants

Compounds of chlorine and bromine are the halogen compounds having commercial significance as flame-retardant chemicals. Halogenated flame retardants can be broken down into three classes: brominated aliphatic, chlorinated aliphatic, and brominated aromatic. As a general rule, the thermal stability increases as brominated aliphatic<chlorinated aliphatic<brominated aromatic. The thermal stability of the aliphatic compounds is such that with few exceptions, thermal stabilizers such as a tin compound must be used. Brominated aromatic compounds are much more stable and may be used in thermoplastics at fairly high temperatures without the use of stabilizers and at very high temperatures with stabilizers.

Antimony oxide is commonly employed as a fire-retardant supplement for halogen-containing polymer systems as a means of reducing the halogen levels required to obtain a given degree of flame retardancy. This reduction is desirable because the required halogen content may be so high that it affects the physical properties of the final polymer. In many cases, the antimony oxide is used simply to give a more cost-effective system.

Additive flame retardants are those that do not react in the application designated. There are a few compounds that can be used as an additive in one application and as a reactive in another. Tetrabromobisphenol A (TBBPA) is the most notable example.

Bis(hexachlorocyclopentadieno)cyclooctane and pentabromochlorocyclohexane are chlorinated compounds used as additive flame retardants.

Oligomeric Flame Retardants. There are several oligomeric flame retardants. The principal advantage claimed for these materials is their resistance to bloom and plate-out. All of the available oligomeric flame retardants are brominated.

Health and Safety

In general, the acute toxicity of halogenated flame retardants is quite low. Continual use of decabromidiphenyl oxide has been placed in question based on the discovery that under certain laboratory conditions brominated dibenzo-*p*-dioxins are generated.

Research sponsored by the Brominated Flame Retardants Industry Panel regarding the use of brominated flame retardants shows that there is no evidence that the use of decabromodiphenyl oxide leads to any unusual risk. In addition, a study by the National Bureau of Standards (now National Institute of Science and Technology) showed that the use of flame retardants significantly decreased the hazards associated with burning of common materials under realistic fire conditions. Work in Japan confirms this finding.

FLAME RETARDANTS: PHOSPHORUS. One of the principal classes of flame retardants used in plastics and textiles is that comprising phosphorus, phosphorus–nitrogen, and phosphorus–halogen compounds. See also **Flame Retardants: Textiles**.

The mode of action of phosphorus-based flame retardants in cellulosic systems is probably best understood. Cellulose decomposes by a noncatalyzed route to tarry depolymerization products, notably levoglucosan, which then decomposes to volatile combustible fragments such as alcohols, aldehydes, ketones, and hydrocarbons. However, when catalyzed by acids, the decomposition of cellulose proceeds primarily as an endothermic dehydration of the carbohydrate to water vapor and char. Phosphoric acid is particularly efficaceous in this catalytic role because of its low volatility. See also **Phosphoric Acid**. Also, when strongly heated, phosphoric acid yields polyphosphoric acid which is even more effective in catalyzing the cellulose dehydration reaction. The flame-retardant action is believed to proceed by way of initial phosphorylation of the cellulose. Certain nitrogen compounds such as melamines, guanidines, and ureas appear to catalyze the cellulose phosphorylation step and are found to enhance or synergize the flame-retardant action of phosphorus on cellulose.

Phosphorus flame retardants can also exert vapor-phase flame-retardant action. Trimethyl phosphate [CAS: 512-56-1], $C_3H_9O_4P$, retards the velocity of a methane–oxygen flame with about the same molar efficiency as antimony trichloride [CAS: 10025-91-9].

Both physical and chemical vapor-phase mechanisms have been proposed for the flame-retardant action of certain phosphorus compounds. Physical (endothermic) modes of action have been shown to be of dominant importance in the flame-retardant action of a wide range of nonphosphorus-containing volatile compounds.

Triphenylphosphine oxide [CAS: 791-28-6], $C_{18}H_{15}OP$, and triphenyl phosphate [CAS: 115-86-6], $C_{18}H_{15}O_4P$, as model phosphorus flame retardants were shown by mass spectroscopy to break down in a flame to give small molecular species such as PO, HPO_2, and P_2. The rate-controlling hydrogen atom concentration in the flame was shown spectroscopically to be reduced when these phosphorus species were present, indicating the existence of a vapor-phase mechanism.

Some claims have been made for a phosphorus–halogen synergism. Antagonism between antimony oxide and phosphorus flame retardants has been reported in several polymer systems, and has been explained on the basis of phosphorus interfering with the formation or volatilization of antimony halides, perhaps by forming antimony phosphate.

Commercial Phosphorus-Based Flame Retardants

A large number of phosphorus compounds have been described as having flame-retardant utility. The compounds demonstrating commercial utility are much more limited in number. They include inorganic phosphorus compounds (red phosphorus, ammonium phosphates, insoluble ammonium polyphosphate, phosphoric acid-based systems for cellulosics), additive organic phosphorus flame retardants (melamine phosphates and other amine phosphates, trialkyl phosphates, dimethyl methylphosphonate, diethyl ethylphosphonate), halogenated alkyl phosphates and phosphonates (2-chloroethanol phosphate (3:1), 1-chloro-2-propanol phosphate (3:1), 1,3-dichloro-2-propanol phosphate (3:1), bis(2-chloroethyl) 2-chloroethylphosphonate, diphosphates, oligomeric 2-chloroethyl phosphate, 2-chloroethyl 2-bromoethyl 3-bromoneopentyl phosphate, oligomeric cyclic phosphonates, pentaerythritol phosphates, cyclic neopentyl thiophosphoric anhydride, aryl phosphates, phosphine oxides), reactive organic phosphorus compounds (organophosphorus monomers, phosphorus-containing diols and polyols, oligomeric phosphate–phosphonate), reactive organophosphorus compounds in textile finishing (tetrakis(hydroxy methyl)phosphonium salts), dimethyl 3-[(hydroxymethyl)amino]-3-oxo propylphosphonate, and phosphorus-containing polymers (polyester fibers containing phosphorus).

Health, Safety, and Environmental Factors

Toxicology. The structure–toxicity relationships of organophosphorus compounds have been extensively researched and are relatively well understood. The phosphorus-based flame retardants as a class exhibit only moderate-to-low toxicity.

A particular mode of neurotoxicity was discovered for tricresyl phosphate that correlated with the presence of the *o*-cresyl isomer (or certain other specific alkylphenyl isomers) in the triaryl phosphates. The use of low ortho-content cresols has become the accepted practice in industrial production of tricresyl phosphate.

Mutagenic and later carcinogenic properties were found for tris(2,3-dibromopropyl) phosphate, a flame retardant used on polyester fabric in

the 1970s. This product is no longer on the market. The chemically somewhat-related tris(dichloroisopropyl) phosphate has been intensively studied and found not to display mutagenic activity. Tris(2-chloroethyl) phosphate appears to be a weak tumor-inducer in a susceptible rodent strain.

There appears to be no documented case of any type of fire retardant contributing to human fire casualties. Most smoke inhalation casualties appear to be caused by carbon monoxide.

Smoke is a main impediment to egress from a burning building. Although some examples are known where specific phosphorus flame retardants increased smoke in small-scale tests, other instances are reported where the presence of the retardant reduced smoke. The effect appears to be a complex function of burning conditions and of other ingredients in the formulation.

Environmental Considerations. The phosphate flame retardants, plasticizers, and functional fluids have come under intense environmental scrutiny. Results published to date on acute toxicity to aquatic algae, invertebrates, and fish indicate substantial differences between the various aryl phosphates. The EPA has summarized this data as well as the apparent need for additional testing.

Tests in pure water, river water, and activated sludge showed that commercial triaryl phosphates and alkyl diphenyl phosphates undergo reasonably facile degradation by hydrolysis and biodegradation. The phosphonates can undergo biodegradation of the carbon-to-phosphorus bond by certain microorganisms.

Uses

The largest volume use of phosphorus-based flame retardants may be in plasticized vinyl. Other use areas for phosphorus flame retardants are flexible urethane foams, polyester resins and other thermoset resins, adhesives, textiles, polycarbonate–ABS blends, and some other thermoplastics.

FLAME RETARDANTS: TEXTILES. As early as the first century BC, Virgil wrote of the treatment of wood with vinegar to impart fire resistance [Sandholtzer]. In the early 1700s a patent was granted for flame retarding cellulose using a mixture containing alum [CAS: 7784-24-9] (aluminum potassium sulfate dodecahydrate), iron(II) sulfate [CAS: 7782-63-0], and borax [CAS: 1303-96-4] (sodium tetraborate decahydrate). In 1821 Gay-Lussac carried out a systematic study of flame proofing using water solutions of ammonium chloride [CAS: 12125-02-9] and ammonium phosphate, or of boric acid and ammonium chloride, to treat cellulosic material such as linen or jute. He concluded that the most effective salts either had low melting points and gave off nonflammable vapors, or they covered the fabric surface with a glassy layer of the salt.

The first known fire-retardant process found durable to laundering was developed in 1912 [Perkin]. A modification of an earlier process, this finish was based on the formation of a tin(IV) oxide [CAS: 18282-10-5] deposit. Although the fabric resulting from treatment was flame resistant, afterglow was reputed to be a serious problem, resulting in the complete combustion of the treated material through smoldering.

A significant advance in flame retardancy was the introduction of binary systems based on the use of halogenated organics and metal salts. In particular, a 1942 patent described a finish for utilizing chlorinated paraffins and antimony(III) oxide [CAS: 1309-64-4]. This type of finish was invaluable in World War II, and saw considerable use on outdoor cotton fabrics in both uniforms and tents.

Work began in the 1930s on the development of flame-retardant cottons based on chemical systems that either reacted directly with the cellulosic substrate, or polymerized on or in the cotton fiber. A serious effort in this direction, mounted from the 1950s through the 1970s, resulted in most of the state-of-the-art flame-retardant finishes for cotton available.

Terminology

Flame resistance and fire resistance are often used in the same context as the terms flameproof and fireproof. A textile that is flame or fire resistant does not continue to burn or glow once the source of ignition has been removed, although there is some change in the physical and chemical characteristics. Although the terms resistant and retardant have similar meanings, flame resistant is normally used when referring to that property of a material which prevents it from burning when an external source of flame is removed; flame retardant is used when referring to the chemicals or chemical treatment applied to a material to impart flame resistance. Flameproof or fireproof, on the other hand, refer to materials totally resistant to flame or fire. No appreciable change in the physical or chemical properties is noted. Asbestos is an example of a fireproof material.

Most organic fibers undergo a glowing action after the flame has been extinguished. From a practical standpoint, flame-resistant fabrics should also be glow resistant because the afterglow may cause as much damage as the flaming itself, in that it can completely consume the fabric.

Another related term is smolder resistance. Smolder resistance implies resistance to ignition by a smoldering source, such as a lit cigarette, placed on the surface of a fabric or in the crevice formed between two butting fabrics. Smolder resistance does not necessarily imply flame resistance, although the material in question may well be flame resistant. A fabric can be smolder resistant and not flame resistant, or vice versa.

Flame Resistance

The flame resistance of a textile fiber is affected by the chemical nature of the fiber, its ease of combustion, the fabric weight and construction, the efficiency of the flame retardant, the environment, and laundering conditions. Fibers are classified into natural fibers, eg, cotton, flax, silk, or wool; regenerated fibers, eg, rayon; synthetic fibers, eg, nylons, vinyls, polyesters, and acrylics; and inorganic fibers, eg, glass or asbestos. Combustibility depends on chemical makeup and whether the fiber is inorganic, organic, or a mixture of both. See also **Fibers**.

The weight and construction of the fabric affect its burning rate and ease of ignition. Lightweight, loose-weave fabrics burn much faster than heavier weight fabrics; therefore, a higher weight add-on of fire retardant is needed to impart adequate flame resistance.

The burning process of cellulose depends on both a source of ignition and the presence of oxygen. A low temperature degradation of cellulose proceeds by the formation of levoglucosan, which in turn undergoes dehydration and polymerization, leading to tars, flammable gases, liquids, and other solids. The flammable gases thus produced ignite, causing the liquids and tars to volatize to some extent. This produces additional volatile fractions which ignite and produce a carbonized residue that does not burn readily. The process continues until only carbonaceous material remains. After the flame has subsided, the carbonized residue slowly oxidizes and glowing continues until the carbonaceous char is consumed.

In general, cotton treated with an effective flame retardant provides the same decomposition products upon burning as does untreated cotton; however, the amount of tar is greatly reduced, with a corresponding increase in the solid char. Consequently, as decomposition takes place, smaller amounts of flammable gases are available from the tar, and greater amounts of nonflammable gases from the decomposition of the char fraction. Char is essentially carbon. Its oxidation causes afterglow. Phosphorus-containing compounds, in some cases polymers, are particularly effective in inhibiting char oxidation. Numerous studies have been made on burning of untreated and flame-retardant-treated cellulose.

Several theories have been postulated to explain the various types of flame retardants for cotton. These theories include coating, gas, thermal, and dehydration or chemical.

Coating Theory. This theory includes fire retardants that form an impervious skin on the fiber surface. This coating may be formed during normal chemical finishing, or subsequently when the fire retardant and substrate are heated. It excludes the air necessary for flame propagation and traps any tarry volatiles produced during pyrolysis of the substrate. Examples of this type of agent include the easily fusible salts such as carbonates or borates.

Gas Theory. The gas theory utilizes two approaches in explaining flame retardancy. In one approach, the flame retardant decomposes to give gases which do not burn. These gases diffuse and mix with the oxygen

present around the combustible cellulosic, thereby protecting it from further combustion. Examples of these gases include water vapor, carbon dioxide [CAS: 124-38-9], sulfur dioxide [CAS: 7446-09-5], and hydrogen chloride [CAS: 7647-01-0]. In the second approach, flame retardants function in the gas phase by producing free-radical terminators when the retardant is heated to flaming temperatures.

Thermal Theory. The thermal approach to flame retardancy can function in two ways. First, the heat input from a source may be dissipated by an endothermic change in the retardant such as by fusion or sublimation. Alternatively, the heat supplied from the source may be conducted away from the fibers so rapidly that the fabric never reaches combustion temperature.

Dehydration or Chemical Theory. In the dehydration or chemical theory, catalytic dehydration of cellulose occurs. The decomposition path of cellulose is altered so that flammable tars and gases are reduced and the amount of char is increased; ie, upon combustion, cellulose produces mainly carbon and water, rather than carbon dioxide and water. Because of catalytic dehydration, most fire-resistant cottons decompose at lower temperatures than do untreated cottons, eg, flame-resistant cottons decompose at 275–325 °C compared with about 375 °C for untreated cotton. Phosphoric acid and sulfuric acid [CAS: 8014-95-7] are good examples of dehydrating agents that can act as efficient flame retardants.

However, it should be pointed out that whereas relatively low levels of applied flame retardant, ie, 2.0%, do inhibit levoglucosan formation, much higher levels, ie, 10.0% or more, are normally required to produce flame resistance. These higher add-ons of flame retardant appear necessary to maximize char formation, thereby imparting flame resistance. In the base-catalyzed dehydration it is postulated that dehydration proceeds with the formation of dehydrocellulose. This is followed by formation of char.

Durability of Retardant Finishes. Fire resistance of a treated cellulosic fabric is reduced when the retardant contains acid groups and the treated fabric is soaked or laundered in water containing calcium, magnesium, or alkali metal ions. Phosphate- and carbonate-based detergents affect durability of fire retardants. Soap-based detergents can result in a substantial loss of fire resistance because of the deposit of fatty acid salts. Phosphorus-based flame retardants are adversely affected by water hardness and laundry bleach, sodium hypochlorite [CAS: 7681-52-9]. Exposure to sunlight and weathering can lead to sufficient loss of flame retardant so that the fabric is no longer flame resistant. Similarly, a combination of sunlight followed by laundering or autoclaving can also lead to loss of flame resistance in a cellulosic fabric.

Nondurable Finishes. Flame-retardant finishes that are not durable to laundering and bleaching are, in general, relatively inexpensive and efficient. In some cases, a mixture of two or more salts is more effective than either of the components alone.

The water-soluble flame retardants are most easily applied by impregnating the fabric with a water solution of a retardant, followed by drying. The water-soluble flame retardants used most widely for textiles are borax, boric acid, diammonium phosphate and sodium phosphate decahydrat.

Semidurable Finishes. Semidurable fire retardants resist removal from 1 to approximately 15 launderings. Such retardants are adequate for applications such as drapes, upholstery, and mattress ticking. If they are sufficiently resistant to sunlight or can be easily protected from actinic degradation, they can also be applied to outdoor textile products. The principal disadvantage of water-soluble flame retardants is their lack of durability. This undesirable property can be overcome by precipitating their inorganic oxides on the fabric.

There are several methods for introducing the insoluble deposits into the fabric structure. The multiple bath method, in which the fabric is first impregnated with a water-soluble salt or salts in one bath and is then passed into a second bath which contains the precipitant, is used most often. Most semidurable retardants used on cotton are based on a combination of phosphorus and nitrogen compounds.

Outdoor Finishes. Excellent fire-resistant fabric has been obtained by treating fabric with a suspension or emulsion of insoluble fire-retardant salts or oxides, e.g., antimony(III) oxide [CAS: 1309-64-4], along with a chlorinated organic vehicle such as chlorinated paraffin.

Two types of flame retardants are preferred for outdoor fabrics, i.e., a system based on phosphorus and nitrogen such as the precondensate–NH_3 finish and an antimony–bromine system based on decabromodiphenyl oxide [CAS: 1163-19-5] and antimony(III) oxide.

The abbreviation for fire, water, weather, and mildew resistance, FWWMR, has been used to describe treatment with a chlorinated organic metal oxide. Plasticizers, coloring pigments, fillers, stabilizers, or fungicides usually are added. However, hand, drape, flexibility, and color of the fabric are more affected by this type of finish than by other flame retardants. Add-ons of up to 60% are required in many cases to obtain adequate flame resistance. Durability of this finish is good and fabric processed properly retains its flame resistance after four to five years of outdoor exposure. This type of finish is suited for very heavy fabrics, e.g., tents, tarpaulins, or awnings.

Test Methods

Numerous tests covering flame retardancy and related matters are available. The requirements most often specified for fire resistance of a textile material are that it must pass either Federal Specification Method 5903 or NFPA 701.

The most extensive body of tests are provided under the auspices of ASTM Standard methods. Specific ASTM test designations and descriptions are available. The other compendium of fire-retardant tests are contained in Federal Test Method Standards 191A.

The oxygen index test (OI) is based on the minimum oxygen concentration that supports combustion of various textile materials. A fabric which would not burn in pure oxygen would have an OI of 1.0. One which would just barely burn in an atmosphere of 20% oxygen and 80% nitrogen would have an OI of 0.20. The higher the OI of a given fabric, the less flammable it is and vice versa.

Types of Retardants

Phosphorus-containing materials are by far the most important class of compounds used to impart durable flame resistance to cellulose. Flame-retardant finishes containing phosphorus compounds usually also contain nitrogen or bromine or sometimes both. A combination of urea [CAS: 57-13-6] and phosphoric acid [CAS: 7664-38-2] imparts flame resistance to cotton fabrics at a lower add-on than when the acid or urea is used alone. Other nitrogenous compounds, such as guanidine [CAS: 133-00-8] or guanylurea, could be used instead of urea. Amide and amine nitrogen generally increase flame resistance, whereas nitrile nitrogen can detract from the flame resistance contributed by phosphorus. The most efficient flame-retardant systems contain two retardants, one acting in the solid and the other in the vapor phase. In some cases, the phosphorus content can be reduced without changing the efficiency of the flame retardant. Bromine in flame-resistant fabric escapes from the tar to the vapor phase during pyrolysis of the textile in air. It appears to have little or no effect on the amount of phosphorus remaining in the char. Bromine contributes flame resistance almost completely in the vapor phase. Another system for making cellulosic fabrics flame-resistant is based on the use of halogens in conjunction with nitrogen or antimony. In the case of systems employing halogen moieties, bromine is more effective than chlorine.

Flame retardant fabrics and finishes include mesylated and tosylated celluloses, urea–phosphate type, phosphonomethylated ethers, amide-based systems, cyanamide, dialkyl phosphite and related retardants (Pyrovatex CP "New", dialkylphosphonopropionamides, triazines), THPC-based retardants (THPC–amide process, THPC–urea–disodium phosphate, THPOH–amide process, THP–amide process), ammonia–gas-cured flame retardants (THPOH–NH_3 process, precondensate–NH_3 process), and pentamethylphosphorotriamide.

Application techniques include radiation and incorporation of flame retardants in fiber.

Flame retardants are used in smolder-resistant upholstery fabric, combination flame retardant–durable press performance, flame-retardant treatments for wool, thermoplastic fibers (Tris, decabromodiphenyl oxide–polyacrylate finishes, Antiblaze 19, nylon finishes), polyester–cotton fiber blends (THPOH–ammonia–Tris finish, decabromodiphenyl oxide–polyacrylate finish, THPC–amide–poly(vinyl bromide) finish, THPOH–NH_3 and Fyrol 76, LRC-100 finish, phosphonium salt–urea precondensate), cotton–wool blends, and core-yarn fabric.

Health and Safety

Because Tris polyester flame-retardant chemical has been demonstrated to be a potential carcinogen, workers in this field have tested a number of commonly used chemicals for potential mutagenicity. Neither the

$THPOH-NH_3$ finish nor its extracts caused a significant systematic increase in mutations when tested by the Ames mutagenicity test.

In February 1978, the Consumer Products Safety Commission approved changes in the FF-3 and FF-5 standards for children's sleepwear. It eliminated the melt–drip time limit and coverage for sizes below 1 and revised the method of testing the trim. This permits the use of untreated 100% nylon and 100% polyester for children's sleepwear.

FLAMINGO *(Aves, Phoenicopteri)*. Large wading birds of several species found in the warm regions of the world with the exception of Australia. They have very long legs and neck and a broad beak bent sharply downward at the middle. Red or rosy shades are characteristic in their plumage. See Fig. 1. Some authorities regard the flamingo as related ancestrally to ducks, geese, and swans. Only in comparatively recent years has the flamingo been placed *Phoenicopteriformes*. Flamingos are considered among the most beautiful of all birds — graceful, friendly, but gregarious. They range in length up to $6\frac{1}{2}$ feet (2 meters) and may be as much as 5 feet (1.5 meters) in height. Although these birds essentially are mute, they do make a chattering noise with their beak, which at times can become quite loud. In flight, the neck stretches forward and the legs slant backward to aid in their streamlining. Like some other water birds, the flamingo has a filtering mechanism as part of its bill. The bill is box-like and can be used in the manner of a scoop. Nests are constructed of dirt and mud in the form of mounds from 12 to 16 inches (30–41 centimeters) in diameter. One or two chalk-white eggs are incubated by both parents. They require from 30 to 32 days to hatch. The chick is downy and able to run around almost immediately after hatching. When sleeping, the flamingo rests on one foot, drawing the other up into the feathers, with the knuckle part sticking out far behind. The flamingo is found from the Bahamas to South America and the Galapagos Islands. Some domesticated flocks are found in Florida. The birds also are found in the high Andes and in parts of France and Spain. The birds often fly in formation. See also **Phoenicopteri**.

Fig. 1. Flamingos.

FLAMSTEED DESIGNATION. A combination of number and constellation name, for example "61 Cygni or 36 Ophiuchi" used to identify naked-eye stars that was adopted by English astronomer John Flamsteed in his stellar catalogue. The numbers were originally assigned in order of right ascension (west to east) within each constellation, but due to the effects of precession they are now slightly out of order in some places. This method of designating stars first appeared in a preliminary version of John Flamsteed's *Historia coelestis Britannica* which was published by Edmond Halley and Isaac Newton in 1712 without Flamsteed's approval. The final version of Flamsteed's catalogue published in 1725 after his death omitted any number designations altogether. The designations gained popularity throughout the eighteenth century and are now commonly used when no Bayer designation exists. See also **Bayer Designation**; **Star**; and **Star Catalogues**.

There are examples of stars bearing Flamsteed designations for constellations in which they do not lie, just as there are for Bayer designations, because of the compromises that had to be made when the modern constellation boundaries were drawn up. It should also be noted that Flamsteed's catalogue covered only the stars visible from Great Britain, and therefore stars of the far southern constellations have no Flamsteed numbers. (Two exceptions are the globular cluster 47 Tucanae and the nearby star 82 Eridani.)

FLANGE. A rim or projection extending completely around the object which is flanged. Thus, a flange is distinguished from an ear, which is a similar projection, but which extends only a small portion of the circumference. Flanges are employed for a great many different purposes, among which is the juncture of adjacent shafts by flanged couplings, the flanges providing area through which connecting bolts may be passed. Flanged wheels are commonly used to maintain the position of a wheel and axle group upon parallel rails; pipe flanges, for the connection of pipes which are not to be welded, or that do not have threaded connections.

Flanges are usually used for pipe sizes larger than 2 inches where disassembly is required. A variety of types and facings is available. Although there is a large amount of metal in a flange, careful and precise machining is required only on the facing. Flanged joints do not require severe diameter tolerances on the pipe. Meticulous alignment before assembly of flat-face and raised-face flanges usually is not required. Assembly and disassembly of flanged piping requires smaller wrenches than for equivalent-size screwed pipe assembly. Flanged-end pipe is furnished in a limited selection of metals. Where the required prefabricated flanged pipe is not obtainable, flanges are attached to the pipe by various kinds of joints. Flanged end fittings and valves are obtainable in most sizes and of most pipe metals.

Welding-neck flanges make possible joints that are as strong as the pipe, both for static and cyclic loading.

A loose flange pipe joint illustrates the general principle of flange construction. See Fig. 1.

FLAPS. See **Aerodynamics and Aerostatics**.

FLARE. A bright, transient event within the sun's chromosphere and corona. Flares produce enhanced emission at radio frequencies and in the ultraviolet and x-ray spectral regions as well. They may also produce increased particle emission, often with ions of cosmic ray energies. Flares usually appear within minutes and fade within an hour. They are localized

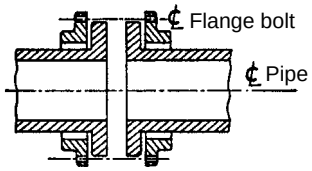

Fig. 1. Flanged pipe joint.

to small areas (typically $<10^{-3}$ of the solar disk) and usually occur within solar active regions.

FLARE ECHO. A weak radar echo in the form of a tapered radial extension beyond the far edge of a severe thunderstorm, associated with the presence of large hydrometeors, especially hail, in the storm.

The phenomenon is explained by what is referred to as "three-body scattering." Some of the radar energy is scattered from the hail region to the ground, reflected back to the hail region, and then scattered a third time, eventually returning to the radar as a weak signal. From the perspective of the radar, the signal travels out and back with a timing indicating that the scattering region is beyond the back edge of the storm. Flare echoes are observed more commonly with radars operating at shorter wavelengths, evidently because of deviations from Rayleigh scattering.

FLARE STARS. These are low-mass main-sequence stars that show erratic changes in their brightness. Changes are sudden, short-lived (minutes), and are unpredictable. Generally, these changes are attributed to local flares on the surface of the stars and have been considered to be similar to large solar flares. The brightness change may range from a few hundredths of a magnitude to 2 magnitudes or more in the visible spectrum. Accompanying this brightness change there has been a similar detectable burst in radio noise from the stars (of the order of 8×10^{-5} watts per square meter per cycle per second). Even the smallest flares observed appear to be more violent than the strongest solar flares by a factor of 10 or more. Best known of the flare stars are red dwarf (or UV Ceti) flare stars. All are also characterized by Ha emission, indicative of strong chromospheres. The nearest flare star is estimated to be about 8.6 light-years (2.6 parsecs) distant from earth. This puts the star at a distance about 0.5 million times as far as the sun is distant from the earth.

A number of these stars show rotationally modulated light variations. These stars, the BY Draconis stars, appear to be members of close binary systems with periods of a few days. Their light variations can be explained well by assuming their surface to be covered with large numbers of sunspots, forming large active regions. The processes occurring in the complex magnetic fields characteristic of such regions could thus also help to explain the observed flaring activity and active chromospheres. They are related to the RS CVn stars which also display enhanced, solar-like, activity.

STEVEN N. SHORE, Socorro, NM

FLASH FLOOD. See **Fronts and Storms**.

FLASHING (Thermal). Liquids may exist with thermal stability at high temperatures provided they are subjected to sufficiently high pressure. Water, for example, may be heated to about 700 °F (371 °C) without boiling if under a pressure of 3,200 psi (217.7 atmospheres). It is true of liquids in general that the lower the pressure on them the lower the boiling temperature and the lower the heat contained in the "saturated" liquid. Thus high-temperature liquids when passed from a region of pressure sufficient for stability into a low-pressure region are not able to contain all the heat originally possessed as heat of fluid, and will be spontaneously partially evaporated by the surplus. This violent readjustment to thermal equilibrium is called "flashing," and is a common occurrence, having many uses and occasionally creating hazards. For example, the destructiveness of a boiler explosion arises mainly from the violence of flashing action, since the water originally contained in a ruptured boiler drum at 600 psi (40.8 atmospheres) pressure suffers an almost instantaneous *four-hundred fold* expansion in volume.

FLASH POINT. The lowest temperature at which an oil will volatilize to yield sufficient vapor to form with air an inflammable gaseous mixture, demonstrable through the production of a flash on contact with a small open flame. The flash point occurs at a temperature lower than the burning point, which is the lowest temperature at which the production of combustible gas occurs rapidly enough to support a steady flame. It is also to be noted that the flash point is the temperature of formation, under the test conditions, of the lower explosive mixture of the substance tested, with air. (The higher explosive mixture is the *maximum* concentration of vapor, with air, which will sustain combustion.)

The flash point is an important characteristic of oils used for various purposes, such as lubrication, because a low flash point indicates the presence or absence of undesirable lower-boiling compounds. On the other hand, the flash temperature is less important then the burning temperature in determining the fire risk of an oil. The flash point is tested experimentally by heating the oil under certain specified conditions in a cup. A thermometer is suspended in the oil so that the temperature may be read during the test. Periodically an open test flame is introduced through an opening in the cover to detect the slight explosive puff which follows when the flash point has been reached. See also **Petroleum**.

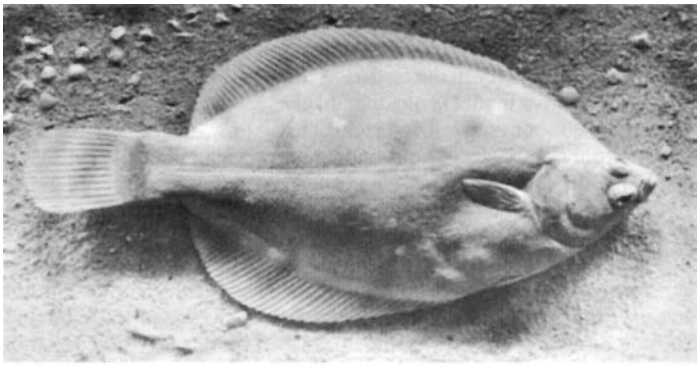
FLATFISHES *(Osteichthyes).* In commercial fishery statistics, a number of fishes, essentially flat in physical form, are lumped together and reported as flatfishes. These include turbot, flounders, halibuts, soles, and plaice. Some of these species are among the most desirable of the fishes for eating fresh or for freeze-preserving.

Flounders. Of the order *Pleuronectiformes*, flounders are distributed in all seas, primarily in warm and temperate zones. A few species are also found in the Arctic and on the borders of Antarctic waters. Some even penetrate fresh water of rivers. Almost all flounders are shelf inhabitants (i.e., shallow seas), and only a few are found at greater depths (down to about 4900 feet; 1500 meters). The size of adult flounders varies from just a few centimeters (i.e., little sole) to several meters. Thus, the halibut, which can attain the length of swordfish and tuna, is exceeded in size only by the whale shark, basking sharks, and the arapaima.

The chief characteristic common to all flounders is the greatly flattened, broadened body. Unlike all other vertebrates, it is not dorso-ventrally oriented (i.e., from back to belly), as in rays, but laterally. This has evolved within the group as an adaptation to bottom dwelling. Flounders may have evolved from species which were similar to present-day perch. When flounder larvae hatch, they look like the larvae of all other fishes. During this planktonic stage, the flounder larvae drift about aimlessly. As they continue growing, they swim in the normal pattern for some time, until metamorphosis begins in the open water, whereby the larva is transformed to a very small flounder-shaped fish. The most striking aspect of this metamorphosis is the migration of one of the eyes from one side of the body to the other; finally, both eyes lie on the same side. This becomes the new upper side of the body, while the eyeless (blind) side becomes the underside. This eye migration occurs shortly before the fishes begin their bottom-dwelling life.

As indicated by Fig. 1, some flatfishes have an uncanny ability to alter their color and pattern to match that of their background. Experimentally, it has been found that this ability is lost when the fishes are blinded and thus this pigmentation accommodation must result from visual stimuli.

Asymmetry of Flounders. Flounders and most other flatfishes have both eyes on one side of the head and in most flatfish species the eyes are predominantly on the left side or the right. For years, scientists have been asking some adaptive reason for this "handedness." For example, what selective advantage is there for the fish in lying on one side rather than on the other? Numerous explanations, some fanciful, have been offered. One journalist (name unknown) reported a number of years ago, "The flounder is the ichthyological acme of lassitude. He begins life swimming in an upright position like any normal fish. Before he is many weeks old, however, he begins to tire in the cosmic struggle for existence. He sinks to the bottom, stretches out on his side and refuses to get up again. In this position he finds himself with one eye staring in the futile fashion into the mud. The eye, apparently tiring in its effort to pierce the primordial ooze, behaves in a manner still unexplained by science. It moves around and joins the other optic, fortunate enough to be on top. This results in the flounder being one of the silliest looking of all fishes, but it also enables him to achieve his aim. In piscine indolence, he lolls on the bottom with



(**a**)

(**b**)

Fig. 1. The flounder can change pattern and coloration to blend with its surroundings: (**a**) Pebble-like markings; (**b**) polka-dotted pattern. (*A.M. Winchester*.)

the misplaced orb and its fellow peering upward for any food that may drift down to him. Even this occasionally wears on the flounder, and when it does he buries himself in the mud where he doesn't even have to look."

D. Policansky (Gray Herbarium of Harvard University) observes that most animals and plants have paired chromosomes and so at each chromosome locus they also have paired alleles, one allele coming from each parent. The alleles in a pair may be the same, in which case the organism is homozygous, or they may be different, in which case it is heterozygous. In the mutant protozoan, the reversal of asymmetry is determined by an allele at a locus named *janus*. In legumes, different alleles found at the same locus determine the direction of pod coiling; the allele for "right-coiling" is the dominant one. Investigators, including the British psychologist M. Annett, have studied, "handedness" in humans. It has been suggested that whereas right-handedness is associated with a "right-determining" allele, there is no "left-determining" allele, but only a neutral allele that does not determine handedness at all. Thus, if both parents have two of the neutral alleles, handedness is not genetically determined — the offsprings have equal chance of being left-handed as they have of being right-handed. M.J. Morgan (University College of London) and M.C. Corballis (University of Auckland) have suggested that all models of asymmetry inheritance should follow that proposed by Annett (the so-called M & C model), that is, one allele coding for directionality and the other allele neutral. Morgan and Corballis have further suggested that even the coding alleles do not intrinsically code for directionality, but instead work on a preexisting gradient of asymmetry in the fertilized egg. Policansky further suggests that an alternative model is one that, in effect, the coding alleles "know the difference" between left and right. That is to say that when the allele at the appropriate locus is right-coding, a right asymmetry results, and that when the allele is left-coding, a left asymmetry results. In either model more than one locus could be involved. In neither has a detailed mechanism of operation been suggested.

In studies of thousands of flounders reared through metamorphosis by Policansky, in an interesting and extensive experiment, he did not note any relation between the side the fish first elected to lie on and the side on which the eyes ended up. In fact, Policansky noted that in some instances the metamorphosing fish continued to swim in an upright position near the top of the tank after the migrating eye had moved all the way to the top of its head. Policansky has summarized his findings (see references) and, in May 1982, concluded, "The only reasonable conclusion appears to be that there is no adaptive difference between left-eyedness and right-eyedness but that the two characteristics are generally associated with some other characteristic, not yet recognized, that does have such significance. If this is the case, the situation is representative of a difficulty commonly encountered by biologists who study evolution; that of deciding which characteristics are adaptive and which are selectively neutral. As far as the difference between left-eyed and right-eyed flatfish species is concerned, this difference, however striking, appears to be an evolutionary *red herring*."

It is interesting to note that the clearest instances of genetic control of left and right asymmetry are found in three species of snails. In the *Lymnaea peregra*, the shell is usually coiled to the right; in *laciniaria biplicata*, the coiling is to the left; in *Partula suturalis*, the coiling may be to the right or to the left. In these snails, the genetic constitution of the female determines the coiling direction. Asymmetries also are encountered in a mutant strain of *Drosophila* (fruit fly), in some protozoa, and in legumes, including common alfalfa.

Witch Flounder. This fish (*Glyptocephalus cynoglossus*) is an important North American species in the inshore gill-net fishery that takes place from fishing communities on the eastern coast of Newfoundland. Typically, the nets are emptied 24 to 48 hours after setting, and the catch immediately returned to modern freezing plants to be iced and processed. The fishery presently takes place during the months of June to October, from close inshore to as far as 50 miles (80 kilometers) from the coast. Traditionally, the market has regarded witch flounder as a premium flatfish with prices paid accordingly.

Turbot. This is a lefteye flounder (*Scophthalmidae*). See Fig. 2. These fishes inhabit the northeastern Atlantic Ocean from Iceland and the Scandinavian coast to the Mediterranean and the Baltic Seas and the Gulf of Bothnia. Its rather thick body is quite wide, with practically a round circumference and a short tail shaft. The eye-side of the body has many bony hooks which develop from modified scales. Turbot, like soles, can change their background color with such success that they are virtual disappearing magicians. The species grows very large. Large turbot are many years old. Sexual maturity appears in the fifth year, at a length of about 1 foot (30 centimeters). Due to intense fishing, very few turbot attain a length of more than double that just mentioned. Most of them are much smaller than that when caught and many are either caught or destroyed prior to spawning.

Fig. 2. Turbot (*Scophthalmus maximum*.)

Turbot was greatly valued in antiquity. Turbot is mentioned in Roman literature as a delightful food. Turbot feed on fishes, such as soles and haddock, and occasionally sand lances, pipefishes, and oceanic gobies. There are several closely related fishes that are of some commercial, often of regional, importance, including the *Black Sea turbot* (*Scophthalmus maeoticus*); the much smaller turbot *S. auosus*, the closest North American relative to turbot; the *megrim* (*Lepidorhombus whiffiagonis*), a turbot distributed on Europe's western coast from Scandinavia to the Iberian Peninsula and off Iceland; the *Norwegian topknot* (*Phrynorhombus norvegicus*), which inhabits the European coasts from Murmansk to southwestern England and is also found off Iceland.

Species of lefteye flounders (*Bothidae*) are numerous. *Scald fishes* (*Arnoglossus*) are widely distributed on northwest European coasts and in the Indo-Pacific ocean. The *Arnoglossus laterna* inhabits the waters from the Oslo Fjord and the British Isles, and across the Mediterranean into the

Sea of Marmara. It is much more slender than turbot species. The *scale fish* (*Bothus*) is distributed primarily along the Atlantic coast of the United States. It is also found westward and southward to the Azores and Angola, respectively. The *Engyproscopon grandisquama* is distributed from the coasts of eastern and southern Africa, Indonesia, Japan, and Australia, and has unusually large scales. This is a very popular eating fish in Japan. A peculiar scald fish (*Pelecanichthys crumenalis*) frequents the Hawaiian Islands, named because its protruding lower jaw is reminiscent of a pelican.

The *summer flounder* (*Paralichthys dentatus*) is one of the best-known species. It is found along the Atlantic coast of North America. Summer flounder (actually a turbot) is a valuable commercial species and exhibits exceptional color transformation. During warm seasons of the year, summer flounder occur in large schools, moving into coastal waters, where they are found on sandy and muddy bottoms. Some even penetrate the fresh water of rivers.

Other valuable commercial species from the same genus include the *California halibut* (*Paralichthys californicus*), from the California coast; *P. olivaceus* from Japan; and *P. microps*, from the coast of Chile.

Halibut. This fish (*Hippoglossus hippoglossus hippoglossus*) is the largest member of the flounder family, reaching lengths up to 7.5 feet (2.3 meters). See Fig. 3. In rare cases, halibut grow to be giants. In 1884, near Hammerfest, Norway, a halibut weighing 528 pounds (240 kilograms) was caught. One specimen caught in 1935 on Iceland's north coast was 12 feet (3.7 meters) long; 17.7 inches (45 centimeters) thick; and weighed 585 pounds (266 kilograms). It was so large that when brought to market there were few bidders for it. The largest halibut ever recorded was 15.4 feet (4.7 meters) long and weighed 726 pounds (330 kilograms). The average length and weight of those presently brought to fish markets are much smaller. The far-flung distribution of halibut extends from Spitzbergen, Iceland, and the Murmansk coast, south to the Bay of Biscay, and in northwestern Atlantic Ocean from southwestern Greenland to Newfoundland.

Fig. 3. Halibut (*Hippoglossus hippoglossus hippoglossus*.)

Not a true arctic species, halibut exists so far north only because it stays warm in the Gulf Stream. This powerful fish is rather elongated, with a tapered head and curved caudal fin edges. The eye-side of the body has a uniform gray-brown to dark olive-brown hue. The underside is white, and the powerful jaws have sharp teeth. While young halibut occur in shallow water, between 115 and 230 feet (35 to 70 meters), the adults are found in depths of nearly 3000 to 3280 feet (700 to 1000 meters). They usually live there above sandy or gravel bottom, very rarely above mud or rocky floors. During summer, halibut prefer the banks of moderately deep to shallow water along the coasts. In winter, they retreat to deeper water.

Halibut carry on extensive migrations between these banks and away from them. They spawn from late December to April, at a water temperature of about 43 to 44.5°F (6 to 7°C). Large females lay up to 3.5 million eggs. They depart from the spawning grounds, which are in the Lofoten-Finnmark region. They migrate northward to Bear Island and into the White Sea, where their feeding grounds are located. Iceland is an important spawning region between February and April. Halibut live for about 25 years. Sexual maturity is attained after 8 to 10 years. Spawning occurs at considerable depths. Eggs have been found between Iceland and the Faroe islands, floating at depths between 1970 and 2625 feet (600 and 800 meters) in water that was 3280 and 6560 feet (1000 to 2000 meters) deep. The halibut diet is quite diverse, consisting chiefly of various fishes, including cod, haddock, scorpion fishes, poachers, grenadiers, herring, sand lances, several flounder species, skates, wolf fishes, and mackerel. Lobsters, large mussels, squid, and echinoderms are also eaten. One marine bird species, the razor-billed auk, has been found in the stomach of a halibut. According to some researchers, halibut can stun or kill small cod by striking them with the tail. Halibut are primarily prey to seals and the Greenland shark. The liver of halibut, which when cooked produces high-quality cod liver oil, is rich in vitamins.

The *Pacific halibut* (*Hippoglossus hippoglossus stenolepis*) is a subspecies of the Atlantic relative and is found in the North Pacific Ocean from the Bering Sea and Alaska to the Sea of Okhotsk and the California coast. It was a favorite catch of the American Indians prior to colonization of North America.

The *Greenland halibut* (*Reinhardtius hippoglossoides*) is a dark, rust-colored (upper side) fish. Distribution of this much smaller species extends across the deeper arctic waters of the northeastern Atlantic Ocean as far east as Novaya Zemlya, around Iceland, and southward to the Norwegian coast. In the northwestern Atlantic Ocean, it occurs from western Greenland southward to the Newfoundland banks. The chief catch areas are near the coasts and in fjords. Greenland halibut feeds primarily on fishes, such as cod, small perches, and on shrimp. Greenland halibut is eaten in large quantities by saddleback seals and belugas.

Fig. 4. Plaice (*Pleuronectes platessa*.)

Plaice. This fish (*Pleuronectes platessa*) is one of the small-mouthed species, all of which are placed in the subfamily *Pleuronectinae*. Plaice is the best-known and most marketed flounder species in some regions. Distribution is on the Atlantic coastal waters from the White Sea and Iceland, and the North Sea and Baltic Sea, to the Gulf of Cadiz in southern Portugal. It is less commonly found in the western Mediterranean. Before heavy fishing started, plaice sometimes reached a length of nearly 3 feet (1 meter). See Fig. 4. In present times of heavy fishing, a plaice that is about 2 feet (61 centimeters) long is considered fairly large. In the North Sea, females attain sexual maturity in their fifth to sixth year. Males generally mature 1 year earlier. Most plaice in the Barents Sea, however, do not mature for 9 to 13 years. In the North Sea, the spawning season occurs from January to March. Large groups of eggs are found in a great depression in the ocean off the Netherlands. One female can lay from 50,000 to 0.5 million eggs in a single spawning period, depending upon her size. Development of the eggs lasts 10 to 20 days, depending upon temperature. The young migrate landward into shallow-water regions. They spend the early part of their life in the tidal zone near beaches. They do not return to deeper water until they have reached a good length. In spite of their limited mobility, plaice form schools and undertake extensive spawning and feeding migrations. The most important component of their varied diet is small mussels. The plaice break mussel shells with their large, powerful throat teeth, a feature characteristic of this species. In the western Baltic Sea, plaice may crossbreed with flounders or dabs.

The *Pacific plaice* (*Pleuronectes pallasi*) is distributed in the northwestern Pacific Ocean and the waters around Kamchatka. It is an important commercial species.

The *dab* (*Limanda limanda*) differs from the plaice, in that it has a rough upper-body surface. Coloration varies from pale-yellow and brownish to a dirty greenish hue. The dab is distributed on the western European coasts of Iceland and from the White Sea to the Bay of Biscay, also penetrating the Baltic Sea and the Gulf of Finland. The dab is most prevalent in the southern North Sea. The species feeds mostly on hermit crabs, isopods, amphipods, echinoderms, mussels, and various worms.

Sole. This fish is of the suborder *Soleoidei* and is another important flounder. Soles not only swim, but also crawl along the floor. Soles are

generally nocturnal. During the day they are deeply buried in mud. With few exceptions, soles are distributed in equatorial tropical and subtropical equatorial waters. A number of species are found in fresh water. The sole (*Solea solea*) is distributed from the Mediterranean and northwestern Africa coasts northward to Trondheim, Norway. It attains a length up to nearly 20 inches (51 centimeters).

Other Flounders. The *smoothback flounder* (*Liopsetta glacialis*) is found around the North Pole along the arctic coasts. It is characterized by a somewhat elongated body and a rather thick, smooth, scaleless zone between the eyes. The species inhabits water very near the freezing point. It is important to regional natives.

The *American winter flounder* (*Pseudopleuronectes americanus*) inhabits the Atlantic coast of North America from Labrador to Chesapeake Bay. This commercially important species is occasionally found in the brackish water of river mouths and, rarely, in the fresh water of rivers. Unlike almost all other flounders, its eggs do not float, but adhere to the floor.

The *North Atlantic flounder* (*Platichthys flesus*) is a well-known flounder species and is found on the coast from the White Sea to the western Mediterranean and Black Sea, as well as far into rivers in fresh water. There are varieties that spend years in rivers. Prior to pollution, one of this species was found in the Thames, upriver from London.

The *starry flounder* (*Platichthys stellatus*) contributes in an important way to the flounder catch off the western coast of the United States. The starry flounder also ascends rivers, far into fresh water.

FLAT PANEL DISPLAY TECHNOLOGY. For this, the 9th edition of VNSE, the editors, with special thanks to Stanford Resources, Inc., San Jose, California, offer a state-of-the-art handbook, as of the year 2000, presented as a family of articles throughout the encyclopedia. The articles may be read in sequence, or separately, as each describes a full-fledged branch of this fascinating and increasingly diverse field. In sequence, the articles are:

- Display Technologies (Other)
- Electroluminescent Displays
- Field Emission Displays
- (Inorganic) Light-Emitting Diode Displays
- Liquid Crystal Display Technology
- Microdisplays
- (Organic) Light-Emitting Diodes (OLEDS)
- Plasma Display Panels
- Vacuum Fluorescent Displays

FLAT-PLATE AREA (Equivalent). That area of an imaginary flat plate, normal to an air stream, whose drag would be the same as that of an actual body at the same air speed is the equivalent flat-plate area of the body. The coefficient of drag of a flat plate is known to vary with the aspect ratio and the area, but it is frequently assumed as 1.28. However, as the area is an imaginary one at all events, the drag coefficient may as well be assumed equal to 1. It is seen that equivalent flat-plate area might have two values, f and f', which are related thus: $f = 1.28f'$.

If D = drag in pounds of a body in air stream of dynamic pressure q,

$$f = \frac{D}{q}$$

$$f' = \frac{D}{1.28q}$$

See also **Aerodynamics and Aerostatics**.

FLATTENING OF THE EARTH. The ratio of the difference between the equatorial radius (major semiaxis) and the polar radius (minor semiaxis) of the earth to the equatorial radius. Also called *compression*. The flattening of the earth is the ellipticity of the spheroid and equals the ellipticity of the ellipse forming a meridional section of the spheroid. If a and b represent the major and minor semiaxes of the spheroid, and f is the flattening of the earth,

$$f = (a - b)/a$$

The magnitude of the flattening is sometimes expressed by stating the numerical value of the reciprocal of the flattening, $a/(a - b)$. See also **Earth**.

FLATULENCE. The accumulation of excessive gas in the stomach or intestine. Causes of stomach gas include: (1) excessive belching which takes in more air than is expelled, (2) consumption of inordinate amounts of carbonated beverages, and (3) swallowing air while eating. Intestinal gas may result from (4) bacterial action on ingested foods, and (5) air that is swallowed and forced into the intestinal tract by peristalsis. Gas also forms in the intestine after abdominal surgery, resulting from a short-term paralysis of the intestinal tract, making it difficult for the patient to pass off the gas naturally. A rectal tube can be used to relieve gas pains of the latter origin. Particular foods, such as raw vegetables, including tomatoes and beans, often will produce excessive gas in the intestine.

A number of preparations are available for the treatment and relief of flatulence. Sometimes various formulations combine antacids with antiflatulents. Generally, the active ingredients of antiflatulents fall into the following categories, which frequently are used in various combinations in a given preparation. (1) Various digestive enzymes, such as: amylase, lipase, protease, and cellulase, among others. Pancreatin from beef pancreas is a source of pepsin, providing multiple digestive enzymes. (2) Simethicone. (3) Bile constituents. (4) Antacids, such as: aluminum and magnesium hydroxide. (5) Sedatives, such as the bella-donna alkaloids hyoscyamine sulfate, atropine sulfate, and scopolamine hydrobromide. These compounds are claimed useful in the relief of variously named conditions, such as dyspepsia, distension, fullness, gastric hyperacidity, mucus-entrapped air or "gas," gastritis, hiatal hernia, peptic ulcer, peptic esophagitis, and common heartburn (pyrosis). Some compounds are not compatible with certain antibiotics, such as the tetracyclines.

Injectable preparations, such as dexpanthenol, are sometimes used immediately after abdominal surgery to minimize the possibility of paralytic ileus.

See also **Antacids**.

FLATWORM (Fluke). See **Fluke**.

FLAVIVIRUSES. The flaviviruses are a group of medically important viruses that are mainly transmitted by mosquitoes and ticks; they include dengue, Japanese encephalitis, St Louis encephalitis, tick-borne encephalitis, West Nile and yellow fever species.

Classification

The family *Flaviviridae* contains three genera: *Flavivirus*, *Pestivirus* and *Hepacivirus*. The names of these genera are derived from the Latin for yellow (*flavus*) and plague (*pestis*), and the Greek for liver (*hepatos*), respectively. The three genera are placed in the family *Flaviviridae* on the basis of similar virion morphology and genome organization. There are no serological cross-reactions between the genera. The *Flavivirus* genus contains 67 human and animal viruses (see below), while the *Pestivirus* genus contains only animal viruses (*Bovine diarrhea*, *Border disease* and *Swine fever/Hog cholera viruses*). The *Hepacivirus* genus currently contains only one member, *Hepatitis C virus*, which infects humans. In addition, on the basis of molecular data, the family also contains three other groups of viruses: *GB virus-A*, *GB virus-B* and *GB virus-C*. *GB virus-A* was identified in New World monkeys, *GB virus-B* in tamarin monkeys and *GB virus-C* in humans (which has also been referred to as *Hepatitis G virus*). The term "flaviviruses," is generally considered to be restricted to the *Flavivirus* genus. *Yellow fever virus* is the prototype member of the *Flavivirus* genus. See also and **Virus**; and **Yellow Fever**.

On the basis of their ecology, flaviviruses have been termed "*arbo* viruses," or arthropod-borne viruses, to denote the fact many are transmitted between vertebrate hosts by mosquitoes or ticks. It should be noted that other groups of viruses are also termed arboviruses, including some members of the *Togaviridae*, *Bunyaviridae*, *Reoviridae* and *Rhabdoviridae* families. Although arboviruses share ecological similarities, they have different virion morphology and genome organization.

Serological relationships between flaviviruses have been determined by antibodies (monoclonal or polyclonal) associated with the biological activities of haemagglutination-inhibition and neutralization, which are both encoded by the E protein. A third method of identification based on complement-fixation activity has been associated with the NS1 protein (Figure 1). The flaviviruses have been termed a "hall of mirrors" by Karl Johnson, owing to the extensive serological cross-reactivities between different flaviviruses. Neutralization tests have been used to identify nine serological subgroups, together with 17 viruses that were not assigned to any serogroups due to poor cross-reactivity with other members of the *Flavivirus* genus (Table 1) [Calisher, et al.:1989]. *Tamana bat virus* and cell-fusing agent have been tentatively classified in the *Flavivirus* genus. The latter is a virus that was isolated from a mosquito cell line.

Recently, nucleotide sequencing of a region of the NS5 gene (Figure 1) of most flaviviruses has resulted in identification of genetic relationships that closely follow those of serological relationships [Kuno, et al.:1998]. However, the genetic analysis has allowed more detailed relationships to be established than was possible by serological studies. In addition, genotypes have been identified for each flavivirus that has been examined. These genotypes tend to relate to the geographic origin of the virus strain. Although genotypes have been reported, each flavivirus exists as a single serotype. Nucleotide sequences for portions of most flaviviruses can be found in Genbank. A list of viruses for which complete genomic sequences have been determined is shown in Table 2.

Names of Viruses. Many of the flaviviruses have been named after the host and/or geographic origin of the virus. This has caused some confusion, particularly within the tick-borne encephalitis serogroup. Originally two types of *tick-borne encephalitis virus* were identified. One was termed Central European, European, Central European encephalitis, or Western subtype, and the other Far Eastern or Russian spring–summer encephalitis subtype. More recently, a third subtype termed Siberian subtype has been described. In addition, Absettarov, Hanzalova, Hypr and Kumlinge were originally considered to be separate viruses. However, these viruses appear to be very closely related or identical to the Central European subtype. They are no longer recognized as distinct viruses, and are considered members of the Central European subtype. Similarly, louping ill has only been described in Ireland and Britain. However, other viruses have been found in Spain, Turkey and Norway that infect sheep or related animals, and are closely related or indistinguishable from *Louping ill virus*. *Negishi virus* from Japan is also thought to be a strain of *Louping ill virus*.

Structure

Morphology. Virus particles are spherical in shape with a lipid envelope; the particles are approximately 50 nm in diameter. The lipid envelope is derived from host cell membranes and constitutes 15–20% of the total weight of the virus particle. Carbohydrates represent 9–10% of the weight of virus particles and are found as cellular glycolipids and viral glycoproteins. Virions contain three structural proteins. The small basic capsid (C) protein surrounds the genome of the virus, and the envelope contains two proteins known as envelope glycoprotein (E) and membrane protein (M). Two types of virions are recognized: mature extracellular virions contain M protein, while immature intracellular virions contain precursor M (prM) that is proteolytically cleaved during maturation to yield M protein. The atomic structure of the soluble form of the E protein (i.e. 80% of E protein) of the Central European subtype of *Tick-borne*

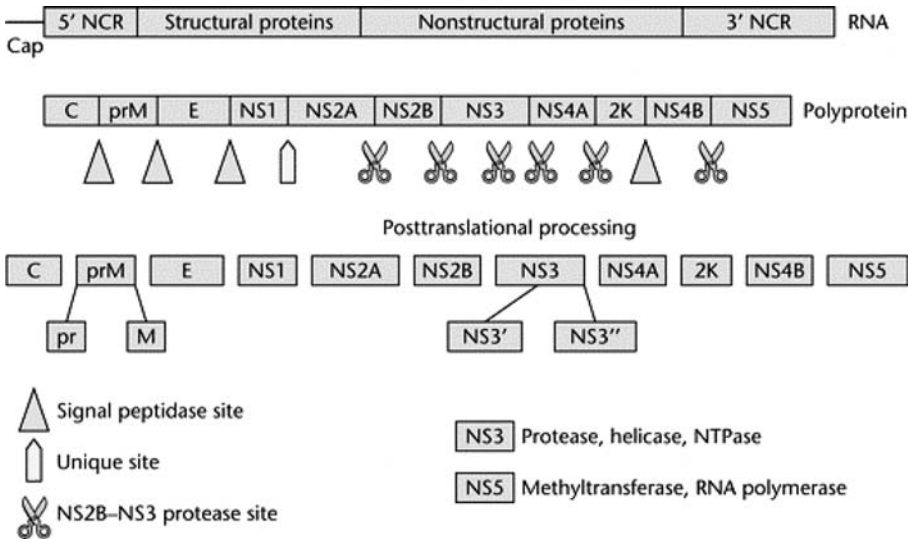

Fig. 1. Organization of the flavivirus genome and expression of proteins (genes are not drawn to scale). NCR, noncoding region; NS, nonstructural; NTPase, nucleoside triphosphatase. NS3' and NS3" have been identified in virus-infected cells but, to date, have not been demonstrated to have functional helicase and/or NTPase activity.

[a] U, unassigned. Viruses shown in bold are prototypes of serogroups.

encephalitis virus has been determined. The E protein forms a dimer that is oriented parallel to the membrane [Rey, et al.: 1995].

Physiochemical Properties. Mature virions sediment at approximately 200 S and have a buoyant density in sucrose of 1.19 g mL^{-1}. Virions are stable at mild alkaline pH (8.0–9.0) but are inactivated by acidic pH, temperatures of 39° C (102 °F) or higher, detergents, organic solvents and ultraviolet light.

Genome. The genome is one positive-sense, single-stranded ribonucleic acid (RNA) of approximately 11 000 nucleotides (i.e. it is equivalent to messenger RNA and infectious). The genes of those flaviviruses that have been sequenced are similar in genetic content, although the 3' noncoding region (3'NCR) (also referred to as untranslated region (UTR)) varies between flaviviruses and strains of a particular virus. The 5'terminus of the genome possesses a type I cap (m-$^{-7}$GpppAmp) followed by the conserved dinucleotide AG. There is no terminal poly(A) tract at the 3' terminus. The gene order is C-prM-E-NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5 [Rice, et al.: 1985]. In the case of *Yellow fever virus*, another NS protein has been identified and termed "2K". All viral proteins are produced as one polyprotein that is posttranslationally processed by viral and cellular proteases.

Structural Proteins. As stated above, the virions contain three structural proteins C, M and E. The C protein has a basic charge to allow it to interact with the genome. The E protein of most flaviviruses is glycosylated at one or two sites, depending on the flavivirus, although some flavivirus E proteins have no glycosylation sites; prM is also glycosylated at one to three sites. The E protein is the viral haemagglutinin (i.e., the protein that binds to red blood cells) and contains most of the epitopes recognized by neutralizing antibodies. Thus, E is the major protein in the virion envelope. The M protein contains a few epitopes recognized by neutralizing antibodies.

Replication

The initial events of the virus replication cycle involve the virus-binding to cell receptor(s) that is mediated by the E protein. Putative cell receptor molecules have been reported but have yet to be confirmed. It has also been demonstrated that, in the presence of subneutralizing concentrations of antibody, virus–antibody complexes can be taken up into cells via binding to Fc or complement C3 receptors. This mechanism is termed "antibody-dependent enhancement" and has been implicated in dengue haemorrhagic fever and dengue shock syndrome. Uptake of the virus particle into cells is via receptor-mediated endocytosis, followed by pH-dependent membrane fusion activity to release the virus nucleocapsid into the cytoplasm.

The input virus does not contain viral RNA-dependent RNA polymerase. Thus, the positive-sense genomic RNA is translated to generate the nonstructural proteins required for replication of the virus, including the RNA-dependent RNA polymerase. RNA replication is associated with membranes and begins with transcription of the input genomic RNA to synthesize complementary negative-sense strands, which are then used as templates to transcribe positive-sense genomic RNAs. These are synthesized by a semiconservative mechanism involving replicative intermediates (i.e. containing double-stranded regions as well as nascent single-stranded molecules). Synthesis of negative-sense RNA continues throughout the replication cycle. Proliferation and hypertrophy of intracellular membranes is a common feature of flavivirus-infected cells, both in cell cultures and in animals. The replication complex sediments with membranous fractions of infected cell extracts.

Translation usually starts at the first initiation codon (AUG) of the single long open reading frame, but may also occur at a second in-frame AUG located 12–14 codons downstream in mosquito-borne flaviviruses. Once the polyprotein has been translated, it is processed by cellular proteases and the viral NS2B–NS3 serine protease (see Figure 1) to generate structural and nonstructural proteins. In addition to the three structural proteins C, prM and E, seven nonstructural (NS) proteins are found in virus-infected cells: NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5. Few of the nonstructural proteins have been studied in detail. NS3 is a multifunctional protein. The N-terminal one-third of the protein forms the viral serine proteinase complex together with NS2B. The C-terminal portion of NS3 contains an RNA helicase domain involved in RNA replication, as well as an RNA triphosphatase activity involved in the formation of the 5"-terminal cap structure of the viral RNA. Two enzymic activities have been assigned to NS5: the RNA-dependent RNA polymerase and the methyltransferase activity necessary for methylation of the 5" cap structure. NS1 is an unusual nonstructural protein as it is glycosylated at one to three sites. The functions of NS2A, NS4A and NS4B are poorly understood [Chambers, et al.: 1990]. However, current evidence suggests that NS2A, NS2B, NS4A and NS5 are all part of the replication complex, and that NS1 is involved in RNA synthesis and virus assembly.

Virus particles can first be observed in the rough endoplasmic reticulum, which is believed to be the site of virus assembly (i.e. interaction of genomic positive-sense RNA molecules with structural proteins C, prM and E). Progeny virions assemble by budding through intracellular membranes into cytoplasmic vesicles. These immature virions (containing prM rather than M protein) are then transported through the membrane systems of the host secretory pathway to the cell surface, where exocytosis occurs. Shortly before virion release, the prM protein is cleaved by furin, or a furin-like cellular protease, to generate mature virions that contain M protein. Immature virions have low infectivity compared with mature virions.

Flavivirus-infected cells also release a noninfectious subviral particle (containing prM and E proteins) that has a lower sedimentation coefficient than whole virus (70 S versus 200 S) and exhibits haemagglutination (hemagglutination) activity (slowly sedimenting haemagglutinin; SHA).

Host cell macromolecular synthesis is not shut off during virus replication and is not decreased until cytopathic effect is evident late in the infection process. In general, mosquito-borne viruses do not replicate in tick cells, and vice versa.

Epidemiology

All flaviviruses infect a vertebrate host, with the possible exception of the cell-fusing agent, which is currently only a tentative member of the *Flavivirus* genus. Some, such as *Japanese encephalitis virus*, are able to infect a wide variety of hosts, including humans, pigs, horses, dogs and monkeys, while others have a very narrow host range and, in the case of dengue, only infect primates. Many flaviviruses also infect haematophagous arthropod species. Approximately 50% of flaviviruses are transmitted by mosquitoes and 28% by ticks; the remaining 22% have no known arthropod vector and are thought to be transmitted by rodents or bats (Table 1).

Arthropods are involved in biological transmission of the virus, i.e. virus multiplies in the arthropod. Specifically, the arthropod acts as a vector to transmit the virus between vertebrate hosts. Most flaviviruses are transmitted horizontally between vertebrate hosts, while some are maintained in nature by vertical (transovarial) transmission. If an arthropod bites a virus-infected vertebrate that has viraemia, the virus is transmitted to the arthropod when it takes its blood meal. Virus disseminates from the midgut to the head. When the arthropod takes its next feed, virus present in the salivary glands is injected into a new vertebrate host. Thus, unlike most animal viruses that are transmitted horizontally between vertebrate hosts, many flavivirus life cycles involve vertebrates and arthropods. As such, there is tremendous selective pressure on these arthropod-borne flaviviruses. Vertebrate viraemias tend to be short-lived, and most flaviviruses have narrow host ranges, i.e. they are only able to multiply in a few arthropod and vertebrate species. The term "vector competence" is used to describe the ability of a vector to transmit a particular virus, and is a combination of physiological, genetic and ecological factors of the arthropod, virus and environment. It should be noted that nonviraemic transmission of tick-borne flaviviruses has been reported, and the life cycles of some flaviviruses are poorly understood. In some areas of the world, dry seasons result in few arthropods, which cause potential breaks in the life cycle described above. In some situations these breaks are avoided by certain viruses being passed transovarially or trans-stadially between arthropods, or by the spread of viruses by migratory birds.

One or more flaviviruses are found in all regions of the world. Mosquito-borne viruses are found in the warmer climates that favor mosquitoes, whereas tick-borne viruses are found in the milder climates that favor ticks. Geographic distributions of particular viruses tend to be related to the geographic distribution of the arthropod and vertebrate hosts, although unknown barriers prevent the spread of some viruses. One of the most famous examples is the lack of *Yellow fever virus* in Asia. The mosquito vector, *Aedes aegypti*, is found in Asia, and laboratory studies indicate that Asian strains of *Ae. aegypti* can transmit *Yellow fever virus*. A number of hypotheses have been proposed to explain this phenomenon, but none have been proven.

Clinical Features

Over half of the members of the *Flavivirus* genus have been reported to infect humans. A number of these are due to laboratory infections before biosafety guidelines were introduced. All flaviviruses are categorized as biosafety level (BSL) 2 ("broad spectrum of indigenous moderate-risk agents that are present in the community and associated with human disease of varying severity"), except for the following:

- *Biosafety level 3* ("indigenous or exotic agents with a potential for respiratory transmission, and which may cause serious and potentially lethal infection"): *Yellow fever*, *Japanese encephalitis*, *Louping ill*, *West Nile*, *Wesselsbron*, *Spondweni*, *Murray Valley encephalitis*, *Powaasan*,

Israel turkey meningoencephalomyelitis, *Rocio*, *St Louis encephalitis* and *Koutango*. *Cacipacore*, *Gadget's Gully*, *Keedougou*, *Meaban*, *Saumaraz Reef* and *Sepik viruses* are also placed in BSL 3 on the basis of insufficient experience and their relatedness to known pathogenic members of the *Flavivirus* genus.

- *Biosafety level 4* ("dangerous and exotic agents that pose a high individual risk of life-threatening disease, which may be transmitted via the aerosol route and for which there is no available vaccine or therapy"): *Tick-borne encephalitis* (particularly *Russian spring–summer encephalitis*), *Omsk haemorrhagic fever* and *Kyasanur Forest disease viruses*.

The above categorization is based on the biosafety levels used in the United States of America (US Department of Health and Human Services). Other countries use similar systems of categorization, but particular viruses may have different biosafety levels.

Flaviviruses have been associated with three disease syndromes: neurotropism, viscerotropism and pantropism. Neurotropic viruses are associated with infection of the central nervous system (e.g. meningitis, encephalitis) and include members of the Japanese encephalitis and tick-borne encephalitis serogroups. Viscerotropic viruses are associated with infection of the liver, kidneys and heart, etc., and include *Yellow fever* and *Kyasanur Forest disease viruses*. Pantropic viruses are associated with infection of many different tissues/organs in the host and include the four dengue viruses. Division of viruses into causing the three disease syndromes above is not absolute. For example, wild-type *Yellow fever virus* is viscerotropic, while the vaccine strains are attenuated but can cause neurotropic disease if they revert to virulence. Of note is the fact that all flaviviruses are neurotropic in rodents and arthropod vectors.

The major human pathogens are *Dengue*, *Japanese encephalitis*, *Tick-borne encephalitis* and *Yellow fever viruses*. A number of flaviviruses have been associated with important veterinary diseases, including *Japanese encephalitis*, *West Nile*, *Wesselsbron*, *Israel turkey meningoencephalomyelitis* and *Louping ill viruses*.

Dengue. Dengue is transmitted by *Ae. aegypti* (and occasionally other *Aedes* species) between primates and is found in all parts of the world where the vector is found, i.e. tropical areas of Asia, Africa, Australia and the Americas. Consequently, it is the major flavivirus disease of humans, and up to 100 million cases of dengue are thought to occur annually. The number of cases continually increases as the geographic distribution of *Ae. aegypti* increases and is coincident with growth in the human population. The disease dengue is caused by four serologically related but distinct viruses termed *Dengue-1, -2, -3* and *-4 viruses*. Dengue fever is a febrile, self-limiting disease in humans, with the virus exhibiting a tropism for mononuclear phagocytes. There are two serious complications of dengue: dengue hemorrhagic fever and dengue shock syndrome.

Infection by one dengue virus results in immunity only against the homologous dengue virus. Different dengue viruses can cause subsequent infections. There is an association between sequential dengue infection and dengue haemorrhagic fever, i.e. infection by one dengue virus followed later by infection with a different dengue virus. Consequently, it is important to distinguish between primary and secondary dengue infections. See also **Dengue Fever and Dengue Hemorrhagic Fever**; and **Hemorrhagic Fewer Viruses**.

Japanese Encephalitis. *Japanese encephalitis virus* is the prototype of the Japanese encephalitis serogroup. It is cause of the most important veterinary flavivirus disease and is the major cause of human epidemic encephalitis in the world. The virus is transmitted by *Culex triaeniorhynchus* (and other mosquito species) between vertebrate hosts; the natural cycle involves water birds. Three vertebrate hosts are considered important: humans, horses and pigs. Humans and horses get encephalitis but are considered to be dead-end hosts owing to low viraemia. The virus induces abortion in pigs, which are considered to be an amplifying host. It is epidemic in temperate regions of Asia and endemic in tropical regions of Asia. Up to 50 000 cases are reported each year. The case-fatality rate varies from 5 to 40% and neuropsychiatric sequelae are seen in 50–70% of survivors.

St Louis Encephalitis. *St Louis encephalitis virus* is a member of the Japanese encephalitis serogroup. The virus is found in North America and tropical South America, and has been isolated from a number of wild animals. The virus is transmitted by *Culex* spp., particularly *C. pipiens* and *C. quinquefasciatus*. Three clinical syndromes have been described: encephalitis, aseptic meningitis and febrile headache. Case-fatality rate increases with age.

Tick-Borne Encephalitis. *Russian spring–summer encephalitis virus* and *Central European encephalitis virus* represent the two subtypes of tick-borne encephalitis that are transmitted by *Ixodes persulcatus* and *I. ricinus*, respectively. A number of rodents act as amplifying hosts. The disease is recognized from Western Europe, including Scandinavia, through Central Europe to Northern China. Central European encephalitis is a milder disease than Russian spring–summer encephalitis, with case-fatality rates of 1–2% and 20%, respectively. Central European encephalitis tends to follow a biphasic course, with symptoms of a febrile illness for 1 week followed by a second phase of central nervous system involvement, including meningoencephalitis. In comparison, Russian spring–summer encephalitis causes a gradually worsening illness, with death taking place within a week of infection.

West Nile Encephalitis. *West Nile virus* is a member of the Japanese encephalitis serogroup. It is transmitted by a number of mosquito species of which *C. tritaeniorhynchus*, *C. univittatus* and *C. pipiens molestus* appear to be the most important. It causes a febrile illness in humans that includes a rash in many cases. Encephalitis and other central nervous system syndromes occur in some cases, and hepatitis has been reported on rare occasions. The virus also causes encephalitis in horses. It is widely distributed in Africa, Asia and Southern Europe. See also **West Nile Virus**.

Yellow Fever. *Yellow fever virus* is the prototype of the family *Flaviviridae*, but is serologically distinct and not placed in any serogroup. The virus is found in tropical regions of Africa and South America and is transmitted between primates by mosquitoes. The main vector in Africa is *Ae. africanus*, while in South America it is *Haemagoggus* spp. *Ae. aegypti* is associated with "urban" yellow fever, the transmission of *Yellow fever virus* between humans. Although urban yellow fever is periodically reported in Africa, there have been no cases of urban yellow fever in the Americas since 1942. *Yellow fever virus* is viscerotropic, with the major target of infection being the liver. Necrosis of the liver results in a loss of liver functions that causes the skin of patients to turn yellow, hence the name given to the virus. Disease symptoms vary from a mild febrile illness to fatality in 10–20% of cases. See also **Yellow Fever**.

Control

There are no antiviral treatments to control flavivirus infections; instead, supportive therapy is the norm. High concentrations of the antiviral agent ribavirin have shown antiviral activity against *Dengue* and *Yellow fever viruses* in cell culture, but this has not been correlated in animal studies. See also **Antiviral Drugs**.

There are licensed vaccines available to control Japanese encephalitis, tick-borne encephalitis and yellow fever; there are no vaccines against dengue. Inactivated vaccines are used for Japanese encephalitis and tick-borne encephalitis. The Japanese encephalitis vaccine is based on strains Nakayama, Beijing-1 or P3. The former two are based on formalin-inactivated mouse brain preparations that are semipurified to remove brain materials, while strain P3 is also formalin-inactivated but is grown in primary hamster kidney cell cultures in the People's Republic of China. The above vaccines require two doses given on days 0 and 14–28 to induce protective immunity, with a booster dose at 1 year and subsequently every 3–4 years to maintain immunity. There is also a live Japanese encephalitis vaccine based on strain SA14-14-2 grown in primary hamster kidney cell culture. This vaccine is only licensed for use in the People's Republic of China. The tick-borne encephalitis vaccine is also formalin-inactivated and based on strains Neudorfl or K23 grown in chicken embryo cell culture. The vaccine is given on day 0 and 14–28 days later. A booster is given 9–12 months later, with further boosters every 3–4 years to maintain immunity.

A live-attenuated vaccine known as 17 D is used to prevent yellow fever. This vaccine was developed in the 1930s by Max Theiler and colleagues and was responsible, in part, for him being awarded a Nobel prize. Theiler and coworkers took the wild-type strain Asibi and passaged it in embryonated chicken eggs to derive strain 17 D after 176 passages. Today, strain 17 D is used as two substrains known as 17 D-204 and 17 DD; both are used as vaccines. One dose of vaccine induces protective immunity. The World Health Organization requires booster vaccination every 10 years but immunity is probably lifelong, as demonstrated by studies in volunteers. The 17 D vaccine is probably the finest vaccine

developed to date. There is a very low rate of reversion to virulence (only 21 cases from over 300 million doses administered), immunity lasts for life and there is no record of a vaccinated individual succumbing to yellow fever. Reversion to virulence results in neurological disease and not the viscerotropic disease shown by wild-type virus. The vaccine is contraindicated for young children under 6–9 months of age because of the risk of postvaccinal encephalitis. See also **Theiler, Max (1899–1972)**.

There are no licensed vaccines to control dengue. Since four serologically-related viruses (dengue-1–4) all cause the clinical disease dengue, attempts to derive vaccines have revolved around a quadravalent vaccine that will control all four dengue viruses simultaneously. The problem of generating a dengue vaccine is complicated by the life-threatening disease, dengue haemorrhagic fever, which appears to be caused by infection with one dengue virus followed by a later infection with a different dengue virus. Clearly, a safe and acceptable dengue vaccine must not prime an individual for dengue hemorrhagic fever. Although the problems of developing a dengue vaccine are complex, candidate live-attenuated vaccines have been developed by passage of dengue viruses in primary dog kidney cell cultures and fetal rhesus lung cell cultures. These vaccines are currently being evaluated.

The mechanism of protective immunity is poorly understood for most flaviviruses, although production of neutralizing antibodies appears to correlate with immunity. Most neutralizing antibodies recognize epitopes of the E glycoprotein. Cell-mediated immunity correlates with nonstructural proteins, in particular NS3. Experimental studies have demonstrated that NS1 can induce protective immunity. The mechanism does not involve neutralization, and is thought to be due to antibody-dependent cell-mediated cytotoxicity or complement-fixing activity of anti-NS1 antibodies.

FLAVONOIDS. A group of aromatic, oxygen-containing heterocyclic pigments widely distributed among higher plants. They constitute most of the yellow, red, and blue colors in flowers and fruits. (Most of the other pigments are carotenoids. See also **Carotenoids**.) The flavonoids include the catechins, leucoanthocyanidins and flavonones, flavanols, flavones, the anthocyanins, and the flavonols. See also **Anthocyanins**.

FLAVORS AND ESSENCES. Normal, healthy people have keen senses of taste and odor, as well as of some of the collateral senses that interact with and contribute to the overall sensations of taste and odor. Much progress has been made over the last few decades in gaining an improved understanding of the physiology and chemistry of these perceptions, but research in the field is mainly of a qualitative and statistical nature. Numerous theories have been developed, but no single theory has been universally accepted. Flavor and essence scientists face tremendous challenges in their attempts to convert an art that dates back centuries into a body of science that can illuminate producers and consumers alike in terms of their odor and taste preferences and dislikes.

The importance of flavor and odor to product successes and failures in the food field alone accounts for an estimated $15–$20 billion loss in profitability by food processors just in the United States.[1] These costs entail the development and premarketing costs that are classified as *nonproductive* when a product does not achieve a close–to–break-even status. This becomes serious when one realizes that, in an average year, 80% of food introductions fail in the marketplace. Other factors, of course, make a product unacceptable, such as texture, dietary content, and appearance, but most experts agree that taste and odor account for a high portion of these failures. As of the early 1990s, it was estimated that approximately 3500 new foods and beverages were introduced into the retail food chain per year.

Well over 5500 compounds have been identified as flavor components of foods.

General Principles of Taste and Odor

The *flavor* of an edible substance is the combined sensation of taste and odor as perceived by the eater/drinker of that substance. Although the components (*flavorings*) are present in food substances, the full aspects of flavor require intimate contact between substance and consumer. The odors emanating from a bakery tend to be richer and more pleasant than the bread itself; the flavor of coffee seldom attains the richness of aroma that one perceives in the vicinity of a coffee roasting plant. Flavor is a unique combination of nerve impulses on the brain centers as the result of actions upon receptors located on the tongue and in the lining of the nose. It is thus the result of interaction between the food substance and the consumer.

Very broadly, tastes can be divided into three, possibly four, categories — *sweet, sour* (or acid), and *bitter* (alkaline) and *salty*. Salty, which for practical purposes is a major component of taste perception, involves physiological differences; in some ways it may be classified as a flavor potentiator.

The manner in which people acquire taste preferences is poorly understood. Sinki (see reference listed) suggests that flavor preference may be explained by:

1. *Genetic factors* (race, sex, individual characteristics, such as acuity, health, and aging);
2. *Physiological factors* (caloric, nutrient, and general health needs); and
3. *Psychological factors*, with three subclassifications:
   a. *Environmental factors* (economic, geographic, legislative, and individual or group habits),
   b. *Personal factors* (nostalgia, religion, attitude, intellect, and belief), and
   c. *Association factors* (as with positive, pleasurable situations or, by contrast, with negative, unpleasant situations, such as illness).

As with other organoleptic senses of humans, the brain's ability to sense a very large variety of tastes, odors, and colors upon exposure is acute, but the ability to recall these sensations is quite limited. For example, the human eye can distinguish several thousand shades of color, but attempts to "remember" or match color samples from sample charts in a paint store is highly inexact.

Practical experience abetted by statistical surveys reveals a wide diversity of taste and odor preferences among peoples worldwide. For example, in studying preferences for flavored yogurt, strawberry is the clear winner in a majority of countries surveyed. Exceptions were a preference for cherry (Germany), citrus (Japan), coffee (Switzerland), and blueberry (Austria). The least preferred flavors were orange, tropical, peach, and banana flavors.

[1] See van Osnabrugge, W., reference listed.

Tastes are also acquired over a period of time. For example, When many North Americans first taste cola drinks or coffee as children or youths, the tastes may be repugnant, but over a period of time these tastes become personal favorites, or they may be shunned for a lifetime. Similarly, many Europeans upon their first exposure to the taste of popular American cola beverages, peanut butter, root beer, and so on, react negatively and may never acquire a real taste for such products. Likewise, flavors such as cassis- or black-current-flavored drinks, which are popular in many European countries, have not enjoyed acceptance in North America.

Over the centuries, humans as well as other animals have learned to associate tastes and odors, in particular, with life-threatening situations. Human excreta, for example, is a foul odor. In some fashion, humans have learned to associate such odors with unpleasant, unhealthy living conditions. The odor of smoke produces dual associations — a log burning on the family hearth, or a burning house or building. The "associative" aspects of odors and tastes remain very poorly understood.

Flavor Characteristic Terminology. The flavorist uses terms (reminiscent of sound harmonics) to describe the roles of certain ingredients in a flavor compound. *Top note* — indicates the flavor first perceived by the food monitor or consumer — and is usually a flavoring substance with a volatility relatively higher than the other flavor components present. *Main note* (sometimes called *middle note*) — is the predominating flavor of the food substance, coming on strong so to speak immediately after sensing the top note. *Bottom note* (sometimes called *undertone*) — flavors that are perceived slightly later in the cycle of tasting or smelling a food substance. An optimal blend of the various notes results in what is sometimes called a *full-bodied flavor*, important, for example, in coffees. Although some of the flavors listed in Table 1 appear immensely undesirable (and often are), sometimes, in the proper combination, they contribute to the desired full-bodied flavor effect. For example, in a garlic flavoring, the characterizing flavor, of course, is garlic. However, an expert panel may detect in a satisfactory product a number of flavor notes, some in addition to or desired in garlic flavor. An expert panel has reported the following flavor notes in such a product: acid, astringent, biting, bitter, boiled, brown, cabbage, earthy, green, heat, iodine, leek, metallic, musty, onion, plastic, potato, rubbery, scallion, sharp, sour, skunky, sulfitic, and toasted.

Role of Odor in Flavor Perception. In terms of total flavor sensation, many authorities agree that odor is usually more important than taste. Experience, of course, demonstrates the marked reduction of flavor sensation when the nasal passages are partially blocked, as in the case of a common cold. In such instances, the layperson may refer to the "flat taste" of the food. In actuality, the taste buds are functioning normally; it is the odor component of flavor that is missing.

The odor component of flavor is made up of at least two vectors. Sniffing a substance without contact with the tongue provides a partial indication of odor, that is, molecular vapors or gases pass directly to the olfactory sensors in the nose via the nasal cavities. This vector might be called the absolute external odor or fundamental odor of a substance. This vector is dependent upon the vapor pressure (volatility) of the food substance itself. The other vector of odor is what researchers call internal odor because the molecules reach the olfactory sensors by way of the pharynx, a flattened tubular passage that connects the back of the mouth with the nasal cavities. In the mouth, the food substance is wetted by saliva, altering not only the vapor pressure of the flavoring agents present, but sometimes exposing more and different flavorings, thus affecting flavor intensity and quality. It is well known, of course, that exceedingly dry substances tend to be odorless or nearly so. The odor of a polished metallic surface, for example, is difficult for most persons to detect. The addition of only modest amounts of moisture to most dry substances significantly increases their fundamental odor, as the result of increasing vapor pressure and by activating all flavoring substances present. The effect of moisture on odor is dramatically illustrated by the dog at the fireside and the dog that has just come in out of the rain.

Classification of Flavoring Substance Sources

There are two fundamental classifications of flavors: (1) *natural*, and (2) *synthetic* or *artificial*. Prior to the early beginnings of organic chemistry (circa 1828), all flavors, essences, aromas, and like substances were derived from naturally occurring materials.

Natural Flavors and Essences. Natural food flavors either occur in nature or are generated during heating or processing by enzymatic reactions or by fermentation.

It is interesting to note that very early civilizations (B.C. and A.D.) gave greater attention to essences than to flavors. In those early times, perfume was considered one of life's few luxuries and, as observed by Tyrrell, ranked higher than learning and many forms of tangible wealth. Early sources of essential oils were derived from resinous gums that exuded from cuts in the bark of certain trees and shrubs. Other odorous substances of antiquity were fruit juices and extracts derived from flowers.[2] Ancient China, Egypt, and India accumulated considerable knowledge for the preparation of pleasant odorous formulations. Such concoctions were used in religious and perfunctory political ceremonies. Also, they were used simply for personal gratification by those who could afford them, as typified today by the large annual expenditures made for perfume and aromatic cosmetics. A major breakthrough in the preparation of aromatics occurred during the Middle Ages when the Moslems discovered the process of distillation for purifying and concentrating odorous substances.

Enfleurage. This is an ancient process for capturing aromatic essential oils from flowers, such as jasmine and tuberose. In this now essentially obsolete process, freshly gathered flower petals are carefully spread on a sheet, usually glass, upon which is spread a very thin film of highly purified fat. The petals remain in contact with the fat film for 24 hours, after which the petals are removed and replaced with a fresh batch. The process requires from 30 to 40 repetitions before the fat becomes saturated with the essential oil. The fat at this point is called *pomade*, which is extracted with pure alcohol. Prior to the availability of more advanced technology, some essence manufacturers would have as many as a thousand petal frames in operation at one time.

Steam Distillation. Although in use for well over a century, steam distillation is still used in some essence plants. The raw aromatic substances are placed in a vessel with water. The steam produced carries the odorous substances and, when condensed, yields essential oil and scented waters. Most installations of this type are found in the underdeveloped countries.

Vacuum distillation is preferred by many flavoring producers because it is more rapid than steam distillation. In this method, the drying and resinification of flavoring constituents is avoided because of the absence of air. The separation of closer-boiling-point materials is more effective under vacuum. Undesirable side reactions between constituents are avoided because of the relatively low temperatures required. Thus, many delicate substances can be handled without thermal degradation.

Rectification (*fractional distillation*) is used generally in those situations where a higher degree of separation and purity are desired. The products are known as *rectified essential oils*. Traces of water, solid and resinous materials, color bodies, and, depending upon the degree of rectification, terpenes and sesquiterpenes may be removed. Properly designed, a fractional distillation system can effect high purity of final product with only a loss of from 1.5 to 2.5% of the quantity of essential oil input. In deterpenization, the terpenes come off as head fractions. Manufacturers of high-quality flavorings generally prefer the well-defined chemical and physical constants obtainable with a terpeneless essential oil.

In rectification, a part of the vapor is condensed and the resulting liquid contacted with more vapor, usually in a column with plates or packing, by returning (refluxing) some of the condensate back to the column. Greater rectification is accomplished where the reflux ratio is high. In a practical way, this arrangement accomplishes what would otherwise require a series of stills in series. Where several fractions (different boiling points) are desired, these can be taken from different plates or height locations of the column. Heavier components, of course, collect in the lower portions of the column.

Molecular distillation is used for certain flavoring substances, such as fruit juice concentrates. This technique is used where the other methods do not effect the separations desired or cause thermal degradation. In this procedure, distillation is carried out at very low pressures (of the order of 0.001 millimeters). A molecular still is distinguished by the fact that the

[2] Additional sources included arils, balsams, barks, beans, berries, branches, buds, bulbs, calyxes, capsules, catkins, cones, flowering tops, fronds, gums, hips, husks, kernels, needles, nuts, peels, pits, pulps, rhizomes, rind, roots, seeds, shoots, stalks, stigmas, stolons thalli, twigs, wood, and wood sawdust, as well as some entire plants.

TABLE 1. (*Continued*)

Jammy	Bitter	Peculiar
Jellylike	Boiled	Persistent
Malty	Broiled	Refreshing
Mapley	Characteristic	Rich
Marshmallowy	Delicate	Roasted
Sacchariny	Fresh	Soft
Sugary	Fried	Strong
Sweet	Full bodied	Tenacious
Vanillic	Grilled	
	Intense	
MISCELLANEOUS	Lingering	
Acidy	Overpowering	
Baked	Overwhelming	

Note: Obviously some of the foregoing terms connote dimensions beyond those strictly conveyed by taste and odor, providing credence to the concept that the total experience of eating or drinking goes well beyond two vectors.

distance from the surface of the liquid being vaporized and the condenser is less than the mean free path (the average distance traveled by a molecule between collisions) of the vapor at the operating temperature and pressure. This distance is usually of the order of magnitude of a few inches (several centimeters). Close separations are often required in the preparation of fractions and isolates of essential oils that are to be used in the preparation of synthetic flavorings.

Extraction. This process was introduced in the early 1900s. The natural raw materials are soaked with an organic solvent. The temperature, time of extraction, and number of extractions required depend upon the solvent used and the characteristics of the raw material. These operating parameters usually are carefully guarded trade secrets. As described by Tyrrell, after maceration, the saturated solvent is filtered and then pumped into the still where 90% of the solvent is evaporated. The final concentration is carried out under vacuum to yield a *concrete* or, where alcohol is used, a *resoinoid*. The concrete normally is a solid waxy mass containing all of the hydrocarbon soluble and odorous matter of the plant. By way of low-temperature washing with alcohol, a waxy substance precipitates out. Subsequent removal of the alcohol at low pressure yields a highly concentrated product known as the *absolute*.

Tinctures, extracts, and absolutes are produced by extraction rather than distillation. A tincture is more dilute than a fluid extract and usually is less volatile. Some food processors prefer these qualities. In other cases, a much more concentrated fluid product (*extract*) or a solid or semisolid (*concrete*) extract is desired. Thus, after filtering, part of the alcohol will be removed by vaporization, leaving a much more concentrated fluid. There are differing degrees of concentration. Most of the familiar extracts found at retailers (almond, lemon, vanilla, etc.) are essential oils dissolved in an alcohol-water mixture.

Oleoresins. To the food processor, an oleoresin represents a flavoring substance midway between the spices and the essential oils. Oleoresins are usually solid and tacky substances at room temperature and soft and sticky at elevated temperatures. Using various spices as starting ingredients, a volatile solvent is percolated through the ground mass, followed by vacuum removal and recovery of the solvent. Generally, oleoresins are uniform and provide a concentrated flavoring power as contrasted with the spices. Oleoresins represent less bulk for the processor to handle (no celluloses, as in spices), but they tend to impart less color to a food product (small quantities required because of flavoring concentration) and not all flavor notes may be extracted during their manufacture. Sometimes the manufacturer will add small amounts of essential oils to their oleoresins to provide a more full-bodied flavoring. Oleoresins are also prepared from some spices, such as turmeric and paprika, not for their flavoring, but more for their coloring. Oleoresins of these two spices are commonly used, for example, in French-type salad dressings.

In numerous instances, additional processing may be required to remove stubborn impurities, waxes, colors, and notably terpene fractions. Solvent extraction is also used in processing herbs and spices to yield oleoresins.

Because the processing of natural substances often involves multi-step operations, costs are generally considered to be higher than a majority of synthesized compounds. A number of natural flavors and essences are given in Table 2, which illustrates the very wide range of ingredient costs.

TABLE 2. COST RANGE OF FLAVORS AND ESSENCES (Scale of 1 (low cost) to 1500 (high cost))

Concentrated Form	Index
Orange oil	1
Grapefruit oil	1
Cedarwood oil	2
Camphor oil	3
Eucalyptus oil	3
Sassafras oil	4
Citronella oil	4
Bitter almond oil	4
Clove oil	5
Cinnamon oil	6
Lemongrass oil	6
Cornmint oil	9
Pettigrain oil	9
Rosemary oil	10
Lignaloe (Boise de rose oil)	10
Anise oil	12
Pine oil	13
Lemon oil	13
Pineneedle oil	14
Onion and garlic oil	16
Nutmeg oil	17
Patchouli oil	17
Lime oil	20
Thyme oil	22
Lavender oil (spike oil)	24
Origanum oil	24
Palmarose oil	25
Caraway oil	26
Bergamot oil	31
Cedar leaf oil	31
Peppermint oil (mentha piperita)	45
Ylang ylang (canaga oil)	53
Geranium oil	60
Cassia oil	67
Vetiver oil	67
Sandalwood oil	110
Orris oil	942
Neroli oil (orange flower oil)	987
Rose oil (attar of rose)	1500

Animal Sources of Flavors and Essences. At one time, animal glandular secretions were widely used in scents, particularly as fixatives. With so much success in synthesis today, coupled with growing empathy for animal welfare, the amounts used of these substances have been significantly reduced. The musk deer (*Moschus moschiferus* L), found in the Himalayan highlands, was at one time a traditional source. The reddish-brown secretion of the male is the odorous principle identified as 3-methylcyclopentadecanonone-one, the principal use of which is in perfumery as a fixative, but which has been reported as an additive in certain food products. There is the civet, *Viverra civetta* Schreber, a cat that lives in Africa and southeastern Asia. The glandular secretion is of main interest in perfumery as a fixative, but it has been reported in foodstuffs

at low levels (about 4 parts per million). There is the beaver of genus *Castor* of the northern climes of Alaska, Canada, and Siberia, the dried and ground glandular secretions of which are also used in perfumery, but also in chewing gum up to concentrations of 400 ppm. The flavoring additive is known as castoreum. And there is beeswax, a crude yellow wax that represents a secondary secretion of the honeybee. In addition to use as a modifier in perfumery, the substance is used up to levels of 5 ppm to enhance the flavor and textural qualities of honey. There always has been a close link between the technology of flavorings for the food field and of fragrances used in perfumes, cosmetics, and related products.

Synthetic (Artificial) Flavors and Essences. Much as the synthesis of aniline (Perkin, England, 1856) revolutionized the textile dyeing industry, the later synthesis of flavors and essences caused a major turn of the aromatics industry. Because of the almost limitless number of organic compounds, artificial equivalents of the natural substances became possible, equally important, entirely new flavors and essences could be created and combined in innumerable ways. Table 3 lists a number of synthetic equivalents or analogues of several natural flavors. Usually the cost of research in finding equivalents and the large number of steps (chemical reactions and separations) required to isolate a given compound are high. Thus, although synthetic or artificial, these compounds are not necessarily less expensive in many instances. Although there are tight regulatory controls to approve the safety of synthetic aromatics and colors, there is a strong preference in the marketplace today for natural flavors where they are in good supply.

Regardless of origin, a large majority of flavor substances are volatile, with a boiling point ranging between 20 °C (68 °F) to 300 °C (572 °F). Most food flavors are lipophilic (affinity for fats) and with molecular weights between 50 and 250. Many foods contain hundreds of different compounds, not all of which, of course, contribute to odor and flavor. For example, over 700 compounds may be found in coffee, but with only a few having significant impact on the flavor profile of coffee.

Compounds that impact directly upon odor or taste are sometimes called "key" compounds. Some of these are listed below:

Apple	ethyl-2-methyl butyrate
Bell pepper	3-isobutyl pyrazine
Butter	diacetyl
Coffee	furfuryl mercaptan
Cucumber	*trans*-2-cis-6-nonadienal
Grape (Concord)	methyl N-methyl-anthrailate
Grapefruit	nootkatone
Mushroom	1-octene-3-ol
Popcorn	methyl-2-pyridyl ketone
Rice (basmatic)	2-acetyl-pyrroline

With the precision characteristic of chromatographic separations, it is self-evident that this instrument has become an indispensable tool for the flavor and essence chemist.

In most European countries, flavors that occur naturally or are generated during heating or processing by enzymatic reactions or modification generally are considered "natural flavors." Flavors that are often referred to in the United States as "synthetic" are usually termed "artificial" in Europe. These would include such compounds as ethyl vanillin, allyl-α-ionone, and ethyl maltol. However, substances that are synthesized but chemically identical to the naturally occurring substances are classified as "natural-identical." This class would include diacetyl, benzaldehyde, anisyl acetate, and benzophenone.

Traditional strawberry flavoring for soft drinks may include amyl acetate, amyl butyrate, butyl isovalerate, ethyl acetoacetate, ethyl butyrate, ethyl caproate, and ethylfuran carbonate — where the beverage is to be sweetened with natural sugar. On the other hand, if synthetic sweetener is used, the formulation will be quite different: aldehyde C_{18}, diethyl acetal, geranil, beta-ionone, maltol, neroli essential oil, octanyl dimethyl acetal, phenethyl alcohol, terpineol, and vanillin. The multiplicity of ingredients to obtain a given flavor is also illustrated by the flavoring substances used in an imitation rose flavor: aldehyde C_8, citral, citronellol, geraniol, linalool, phenethyl alcohol, and rhodinol. Many scores of additional examples of this nature are given and excellently described in the Fischetti reference listed.

Flavor and Essence Research. Successful food processors realize how important the selection of flavoring ingredients is to the ultimate success of a product in the marketplace and consequently support flavor research and extensive premarketing testing prior to introducing a new product nationwide or worldwide. Much of the basic flavor research is carried out by flavor manufacturers, as exemplified in the United States by member firms of FEMA, as previously mentioned. The costs for such research, of course, become part of the price for flavor ingredients. These costs, coupled with the cost of chemically processing many flavor and essence ingredients, whether obtained from natural sources or synthesized, can become quite high and measured in terms of $ /ounce or $ /gram. On the other hand, many ingredients can be quite inexpensive, as previously shown in Table 2.

Some flavor and essence research also is conducted at the university level. For example, the Monell Chemical Senses Center (affiliated with the University of Pennsylvania) is renowned worldwide for its scientific approach to a better understanding of the human senses of taste and odor.

Although odor (essence) is an important part of flavor sensitivity, there are numerous inedible consumer products where olfactory sensitivity is the principal concern. In addition to perfumes, soaps, hair sprays, and other cosmetics, odor is important to the acceptability of laundry and cleaning products, polishes and waxes, and decorative materials. Deodorizing agents also fall within this general sphere of interest.

The general steps involved in flavor and essence research, as suggested in a "Scientific Status Summary" prepared by the Institute of Food Technologists' (IFT) Expert Panel on Food Safety and Nutrition, include the following:

1. Selection of sample containing target flavor.
2. Isolation, concentration, and preliminary fractionation.
3. Final separation.
4. Synthesis of authentic compound.
5. Confirmation of identification.
6. Sensory evaluation.
7. Data interpretation.

The ultimate objective of flavor research is to understand the biological pathways leading to the formation of the compound, as well as the chemical mechanisms responsible for the development of objectionable flavors in agricultural and ocean produce.

An interesting example is given in the IFT Report. In the flavor analysis of packaged potato chips, 2,5-dimethylpyrazine, along with a number of other pyrazine compounds, was identified. For certain foods, the pyrazines are a major class of flavor ingredients. Thus, in seeking aroma and flavor improvement, numerous combinations and proportions of various pyrazine compounds were tested in an effort to find the most effectively pleasing formulation.

Flavor research owes much to the science of chromatography, which made its appearance a relatively few decades ago. Stofberg observes that more than 5000 compounds have been identified as flavor components of foods. The Fischetti reference listed contains exhaustive listings of these compounds and their properties.

New Paths in Flavor and Essence Research. Although much research continues in the search for new, more promising, and sometimes less expensive substitutes, a considerable portion of research today considers a number of other factors that shape the taste and odor profile of a product. For example, studies are directed toward better understanding the interactions of flavor compounds with other chemical compounds in the final product or during processing, such as during preserving, baking, or sterilizing. Interactions with carbohydrates, proteins, fats, and enzymes are among these objectives. Chang also mentions two additional areas of technology that will contribute to advances in flavor technology. These include biotechnology, which is bringing such techniques as genetic engineering (recombinant DNA) and plant tissue culture to flavor research. The other major development is supercritical fluid extraction (SFE), which will impact on fermentation and enzymatic modification as flavor-creating sources. Chang notes that the use of SFE will produce essential oils with a higher yield and improved quality as compared with traditional extraction with organic compounds. However, SFE equipment is more costly.

Carbohydrates and Flavor Development. In considering the flavor of food products, the researcher must be concerned not only with achieving flavor by adding natural or synthetic flavoring substances, but also with biochemical processes that may occur during processing, storing, and later heating or cooling of the product just prior to serving the product. Inasmuch as carbohydrates predominate in many food products, this is a class of

TABLE 3. SYNTHETIC EQUIVALENTS (APPROXIMATIONS OR ANALOGUES) OF VARIOUS NATURAL FLAVORS

Almond	Tolualdehyde (*o*, *m*, *p*)
Apple	Allyl butyrate, cyclohexylvalerate, isovalerate, propionate; Benzyl isovalerate; Butyl isovalerate, valerate; Cinnamyl formate, isobutyrate, isovalerate: Citronellyl isovalerate; Cyclohexyl acetate, butyrate, isovalerate: Ethyl isovalerate, valerate; Isopropyl acetate, valerate; 2-Methylallyl butyrate; Methyl butyrate; Terpenyl isovalerate.
Apricot	Allyl butyrate, cyclohexylcaproate, cyclohexylvalerate, propionate; Amyl phenylacetate; Benzyl formate, propionate; Butyl propionate; Cinnamic acid; Citronellyl acetate: gamma-Decalactone; gamma-Dodecalactone; Ethyl cinnamate; Geranyl butyrate, isobutyrate, isovalerate. Heptyl acetate, propionate; Methyl ionone; Phenylethyl dimethyl carbinol; Phenylpropyl alcohol; Propyl cinnamate; Santalyl acetate; Tetrahydrofurfuryl propionate; gamma-Undecalactone.
Banana	Cyclohexyl acetate, butyrate, propionate; Ethyl valerate.
Butter	Diacetyl.
Caramel-Butterscotch	Maltol.
Caraway	D-carvone.
Cheese	Hexanoic acid; Isovaleric acid (rancid).
Cherry	Allyl benzoate; Anisyl butyrate, propionate; Cyclohexyl cinnamate, formate; Methyl anthranilate; Rhodinyl formate; Tetrahydrogeraniol; Tolualdehyde (*o*, *m*, *p*).
Chocolate	Tetrahydrofurfuryl propionate.
Cinnamon	Cinnamaldehyde; Alpha-methylcinnamaldehyde.
Citrus	Decanal dimethyl acetal.
Cloves	Methyl cinnamate; isoeugenol.
Cocoa	Neryl butyrate; Phenylpropyl cinnamate.
Coconut	Allyl undecylate; Ethyl undecylate; Methyl undecyl ketone; gamma-Nonalactone; gamma-Octalactone.
Cognac	Allyl pelargonate; Cyclohexyl caproate.
Cola	2-Ethyl-3-furylacrolein.
Currant	Cyclohexyl butyrate; Guaiol acetate (black currant); Linalyl acetate, isobutyrate, propionate (black currant); Methyl ionone; Methyl propionate (black currant).
Fatty	Decanal; Ethyl nonanoate; Heptyl alcohol; Lauryl alcohol, aldehyde; Nonanal; Octanal; 1-Octanol; Undecanal; 10-Undecenal.
Flowery	Anisyl alcohol; Benzyl acetate, phenylacetate; Cinnamic acid; Cinnamyl acetate; Citronellyl formate; Cresyl acetate; Decanal; Dimethyl benzyl carbinol; Dimethyl benzyl carbinyl acetate; Ethyl anthranilate; Geranyl acetate; Hydroxycitronellal dimethyl acetate; Linalool; Linalyl acetate; Methyl benzoate; Penethyl acetate; 2-Phenylpropionaldehyde; 3-Phenylpropionaldehyde.
Flowery/Fruity	Anisyl acetate; Cinnamyl isovalerate; Citronellyl; Ethyl laurate, octanoate; Geranyl butyrate, propionate; Nonyl acetate.
Fruity	Benzyl propionate; Butyl acetate; Cinnamyl anthranilate, formate; Citronellyl acetate, butyrate, isobutyrate; propionate; Delta-decalactone; Diethyl malonate; Dimethylbenzyl carbinyl acetate; Delta-dodecalactone; Ethyl *p*-anisate, benzoate, butyrate, heptanoate, hexanoate, maltol, nonanoate; Isoamyl butyrate, hexanoate, isovalerate, cinnamate; Linalyl isobutyrate, propionate; Maltol; Methyl benzoate, cinnamate; 2-Methyl-undecanal; Nerolidol; Octanol; Octyl formate; Phenethyl isobutyrate, isovalerate; gamma-Indecalactone.
Grape	Allyl salicylate; Cinnamyl anthranilate; Guaiol acetate; Isobutyl anthranilate; Isovalerophenone; Octyl isobutyrate; Phenylpropyl acetate, ether.
Grapefruit	Styralyl acetate.
Green Leaves	Allyl anthranilate
Hawthorne	Acetanisole; *p*-Methoxybenzaldehyde.
Heliotrope	Piperonal
Honey	Allyl phenoxyacetate, phenylacetate; Benzyl cinnamate; Carvacryl acetate; Cinnamyl butyrate; *p*-Cresyl acetate; *p*-Cresyl ethyl ether; *m*-Cresyl phenylacetate; *p*-Cresyl phenylacetate; Cyclohexyl phenylacetate; Ethyl phenoxyacetate, phenylacetate; Guaiol phenylacetate; Isobutyl phenylacetate; Linalyl butyrate; Methyl phenylacetate; Phenethyl acetate, butyrate, phenylacetate; Phenylacetic acid; Propyl phenylacetate; Santalyl phenylacetate.
Lemon	Citral; Citronellal.
Licorice	Methylcyclopenteneolone.
Maple	Methylcyclopenteneolone.
Melon	Cinnamaldehyde; Ethyl hexadienoate; Methyl amyl ketone; Octyl butyrate.
Menthol	3-*p*-Methanol.
Mushroom	Hexyl furan carboxylate.
Mustard	Allyl formate.
Orange	Linalyl anthranilate.
Peach	Allyl cyclohexylcaproate, cyclohexylvalerate, undecylate; Amyl phenylacetate; Anisyl alcohol, butyrate; l-Citronellol; Cyclohexyl caproate, cinnamate; gamma-Dodecalactone; Ethyl cinnamate; Isopropyl benzyl carbinol; Methyl methylanthranilate; Methyl nonyl ketone; Methyl octine carbonate; gamma-Octalactone; Oxyl acetate; Phenethyl alcohol, isovalerate, salicylate; Phenylallyl alcohol; Phenylpropyl isobutyrate; Propyl cinnamate; Rhodinyl formate; gamma-Undecalactone.
Pear	Benzyl butyrate; 2-Ethylbutyl acetate; Ethyl heptylate; Hexyl acetate; Hexyl furan carboxylate; Isoamyl acetate; 2-Methylallyl caproate; Methylheptenone; Propyl acetate.
Pineapple	Allyl caproate, cyclohexylacetate, cyclohexylbutyrate, cyclohexylpropionate, 2-nonylenate, phenoxyacetate; Benzyl formate; Bornyl acetate; *n*-Butyl acetate; Butyl isobutyrate; Cinnamyl acetate; Decanal dimethyl acetal; Ethyl butyrate, hexadienoate, phenoxyacetate; Hexyl butyrate; 2-Methylallyl caproate; Methyl beta-methylpropionate; Methyl undecylate; Propyl isobutyrate.
Plum	Butyl formate: Citronellyl butyrate, formate, propionate; gamma-Decalactone; Guaiol butyrate; heptyl formate; Hexyl formate; Isoamyl formate; Isopropyl formate, propionate; Linalool; Neryl propionate; Phenethyl formate (green plum); Phenethyl isobutyrate (green plum); Phenylallyl alcohol; Phenylpropyl butyrate; Propyl formate; Terpenyl butyrate.
Raspberry	Benzyl salicylate; alpha-Ionone; Isobutyl cinnamate; Methyl ionone; Neryl acetate; Santalol.
Rose	Phenethyl alcohol; Phenethyl dimethyl carbinyl isovalerate; Rhodinol.
Rum	Ethyl formate; isobutyl formate.
Sassafrass	*p*-Propyl anisole.
Spearmint	1-Carvone.
"Spice"	Eugenol; Isoeugenyl acetate; 3-Phenylpropyl acetate.
Strawberry	Anisyl formate; benzyl isobutyrate; Cuminic alcohol; Ethyl methylphenylglycidate; Ethyl phenylglycidate; Isoamyl salicylate; Isobutyl anthranilate; Methylacetophenone; Methyl cinnamate; Methyl naphthyl ketone; Nerolin; Neryl isobutyrate; Phenylglycidate
Vanilla	Propenyl guaiethol; Vanillydene acetone.
Violet	alpha-Ionone; beta-Ionone; Methyl-2-octynoate.
Walnut	gamma-Octalactone.
Wine	Ethyl acetate; heptylate.
Wintergreen	Allyl salicylate; Methyl salicylate.

chemical substances that has received much attention. The flavor scientist must distinguish the simple sugars from the complex polysaccharides. These types of compounds differ widely in their functional properties. While the simple carbohydrates consist of mono- and disaccharides, the complex polysaccharides include, for example, gums and hydrocolloids.

As pointed out by Godshall (Sugar Processing Research, Inc.), sweetness is a primary functional property of the common simple carbohydrates, including sucrose, glucose, fructose, and lactose. Sometimes this flavor is referred to as "pure sweet," with a relative sweetness value arbitrarily set at 100 for comparing the sweetening power of other carbohydrates. This value usually is fixed at 100 when comparing the high-intensity sweeteners with sucrose. See also Sweeteners. With the exception of fructose, xylitol, and invert syrup, sucrose is the sweetest of the common carbohydrates. Some sweeteners exhibit surprising performance. For example, glucose has

a property of "self-potentiation"—that is, at concentrations of 2–10%, it has a sweetness index of 50 to 60, whereas at concentrations of 50–60%, the sweetness index rises to 90 to 100. Fructose, although sweeter than sucrose in solution, is essentially no sweeter than sucrose in baked goods. The molecular structure of closely related sweeteners also affects taste. For example, beta-glucopyranose is only about two-thirds as sweet as alpha-glucopyranose.

Advantage can be taken of what may be termed sweetness synergism. For example, Godshall cites glucose-sucrose mixtures that can be 20–30% sweeter than either constituent alone of similar concentration. A number of substances have the property of suppressing sweetness. Carbohydrates, such as guar gum, cornstarch, and carboxymethylcellulose, suppress sweetness, particularly of sucrose.

The food flavorist also must be aware of metal complexes, which carbohydrates are capable of forming. Iron salts not only form complexes with dietary fiber, but with nearly all of the known natural sugars. Fructose, maltitol, sorbitol, and xylitol can easily form complexes with the ferric ion. In the same manner, formation of complexes can help to minimize unpleasant metallic tastes.

Carbohydrates characteristically absorb volatile substances from the environment, and they also retain their volatility, even under drying cycles. Flavorists have taken advantage of these properties, purposely using sugars and polysaccharides as flavor "carriers," which is of particular interest in making stable, dry, and flowable flavor powders.

Flavor chemists also are aware of the Maillard or browning reaction, which can occur in food products as caused by the condensation of an amino group by a reducing sugar. This is a non-enzymatic reaction, the effects of which have been studied, both on flavor and color, each of which can be desirable or harmful, depending upon the food product. For example, the browning reaction is favorable in the flavor development of aroma in baked bread, roast meat, coffee, chocolate, toasted nuts, baked potatoes, and maple and cane syrups. However, browning in such products as milk powders and dried orange juice are highly undesirable.

Encapsulated Flavors. Modified procedures during the past decade have permitted the preparation of encapsulated flavors with flavor levels over twice that of prior available products. Spray drying has been the principal key to this success. First, an oil flavor is emulsified into an aqueous solution or is dispersed in an edible carrier material, after which the emulsion is pumped through an atomizer into a high-temperature chamber. The water evaporates rapidly, and particles of carrier material are formed around the flavor. However, some of the flavor component reaches the surface of the product. This requires the addition of antioxidants to suppress oxidative changes in the flavor ingredient.

Even more recent has been the introduction of encapsulation/extrusion, which also permits conversion of flavorants, such as essential oils, into solid form. Spray drying is not required. In the encapsulation process, the flavor substance is "enrobed." A viscous carbohydrate, with less than 10% water, is created by heating, after which an emulsifier and acid flavoring ingredients are added. The ingredients are reacted under pressure in a cool alcohol bath, and then the product is extruded to form filaments. Thus, the final easy-to-handle product contains the flavor within a small capsule.

Effects of Microwaves on Flavors. When microwave cookery was introduced, it added another dimension to the food flavorist's concern. When one first uses microwave heating for foods, the rate at which different food substances increase in their temperature for a given intensity and time of exposure is readily noticeable. This phenomenon, of course, is not present when conductive or convective heating is used. Like water, most flavor components are polar molecules and tend to be vaporized and thus lost; the flavors that are not lost may be somewhat decomposed and thus distort the flavor effect intended. Among the common flavorings used, there is a considerable difference in their performance when subjected to microwave radiation. Generally, a microwavable food product enjoys a distinct advantage in the marketplace. Thus, flavoring formulations must be adjusted so that flavor will be retained, regardless of the manner in which the product is heated.

In researching this problem, one flavor supplier tested more than 500 chemicals, solvents, essential oils, and natural raw materials (acids, aldehydes, ketones, esters, lactones, amines, thio compounds, and hydrocarbons), which may be used in varying amounts in compounding complex flavors. By way of testing these materials at various powers in the microwave oven, values representing the ratio of the temperature increase of the sample to the temperature increase of a standard (water) were established. These data have been quite useful in compounding flavors for microwave-able foods.

The research indicated that comparatively few common flavorings absorb heat (thus, temperature rise/unit of time) as fast as water. Among the more volatile under microwave radiation are fenugreek and onion oleoresin, whereas, in decreasing order of volatility, are sage oleoresin, ginger oleoresin, carrot seed oil, anise oil, basil sweet oil, oleoresin celery, and oleoresin black pepper.

As part of the testing program, two lemon flavors were considered for addition to a microwave-able cake mix. The test showed that one flavor (highly concentrated in citral) became extremely hot and produced over ten chemical by-products, with consequent serious change in the flavor profile. By contrast, a flavor precisely engineered for microwave heating retained its integrity and consistency throughout the baking process. Further details are given in Pszcaola reference listed.

Spices and Seasonings

These products may be defined as dried aromatic substances (natural) used to season food products. They play an important role in seasoning, but also are frequently used for their food coloring power as well as their effects on other properties, such as texture. Spice science traditionally is treated as a subscience of that pertaining to flavors and essences. See also **Spices and Seasonings**.

Regulations and Labeling of Food Flavors. Government regulation of flavor additives for foods range considerably from one country to the next. In the United States, the Food and Drug Administration (FDA) prevails. In addition to testing new flavors, the FDA is assisted by an independent expert panel, made up of expert toxicologists, pharmacologists, and biochemists. Industry self-policing is provided by the Flavor and Extract Manufacturers Association (FEMA). Flavors fall within the province of the 1938 Federal Food, Drug, and Cosmetics Act. Premarketing safety evaluations and clearance by the FDA were not required by law until 1958, when an amendment to the Act was passed by the U.S. Congress.

At that time the GRAS (Generally Regarded as Safe) classification was also provided. The criterion for GRAS: "Chemicals normally present in food consumed by man through the ages without any apparent adverse effects can be presumed to be safe at the concentrations found in those foods." The sound basis for the GRAS classification is reflected by the fact that only ten substances, among many hundreds, have been removed from the GRAS classification over a period of nearly 50 years.

The primary concern of regulation has been and continues to be the banning of substances that may induce cancer in people and animals. Labeling regulations for food flavors require that one or more designations should appear on the food container: Spice, Natural Flavor, and Artificial Flavor.

The aforementioned regulations also apply to other food additives, such as colors, texturizing agents, and emulsifiers.

In food products, the concentration of flavor substances ranges from a few parts per million (ppm) to about 100 ppm, with the concentration of individual compounds as low as parts per billion (ppb) or even parts per trillion (ppt). Such concentrations can be determined today by chromatographic techniques. Of course, sugar (sucrose and others) are used in much higher concentrations, particularly in baked goods, jellies, jams, fruit drinks, and cured meats, among others. In many foods, sugars contribute in a major way to other properties, such as texture, moisture retention, and resistance to spoiling over extended periods.

Physiological Aspects of Flavors and Essences

Receptor cells especially sensitive to chemicals are found in virtually all animals. By convention, those receptors normally excited by contact with chemicals in liquid phase at relatively high concentrations are termed taste or *gustatory receptors*, although the distinctions between taste and smell are not critical at cellular or molecular levels.

Physiologists use the term *papillae* to identify so-called taste buds on the surface of the tongue. There are several thousand papillae on the human tongue. Because the tongue takes so much abuse when a person is eating a variety, often very coarse and rough foods, some authorities believe that the papillae are constantly being renewed. Small fibers, almost like tiny hairs, extend from these cells to the surface of the tongue. Some investigators have described the papillae as being of three general shapes: those that look like tiny mushrooms; those that appear like miniature

hills with moats around them; and the tiny threads and cones. Observable differences in shape tend to reinforce earlier theories, which embrace the use of differently structured organisms to sense different taste categories, notably the traditional four basic taste sensations — sweet, sour, bitter, salty. These concepts have been difficult to refine or confirm.

Chemical aspects of taste receptor functions can be studied by recording the patterns of electrical potentials in receptor cells while the cells are being stimulated with pure chemicals of known structures and properties. Since the mid-1950s, when this method was first successfully applied to single taste receptor cells, using receptors on the mouth parts of a fly, many earlier theories of taste stimulation have been revised.

Intracellular recordings from taste cells of rat and hamster show that even primary receptor cells are sensitive to three or four of the so-called basic taste modalities. Consequently, it is generally held that a variety of different receptor *sites* commonly exist on the receptor membrane of any one receptor cell. Biochemical characterization of events at receptor sites has progressed in analyzing electrolyte and carbohydrate stimulation.

Electrolyte stimulation is chiefly a function of monovalent cations in all animals that have been studied. Consequently, the receptor sites are thought to be anionic. The pH relationships of stimulation also indicate that strongly acidic (e.g., PO_4^{2-} or SO_4^{2-}) receptor groups are involved. Calculations of free energy changes of the reaction between salt and receptor site give values between 0 and -1 kcal/mole; and low ΔF values suggest that the reaction involves only weak physical forces. The reaction occurs extremely rapidly, since typical nerve impulses can be recorded within 1 millisecond after stimulating electrolytes are applied. In blow-flies, 0.004 M NaCl, which produces 1 impulse per second, represents the threshold for behavior response. These thresholds appear to be somewhat higher in humans.

No one type of receptor site or reaction can account for the extreme structural specificities observed. A curious assortment of molecules can elicit "sweet" sensations. Early studies on a variety of organisms demonstrated that ring structures and D-isomers were more stimulating in polyol compounds than straight-chain and L-isomers. Thus, inositol (Fig. 1), with its ring structure, was found to stimulate. The straight-chain polyhydric alcohols sorbitol, dulcitol, (Fig. 2), and mannitol did not stimulate. Possession of an alpha-D-glucopyrano side linkage was found to generally increase the stimulating capacity of sugars. Maltose, with a 1,4-linkage; turanose, with a 1,3-linkage; and the nonreducing sugars stimulate. Lactose, with its 1,4-linkage, and melibiose, with a 1,6-linkage, both lack the alpha link and are relatively nonstimulating.

Conformation, as well as configuration, is important in determining the stimulating power of sugar molecules. Glucose, which exists in solution almost entirely in an aldopyranose "chair" formation has derivatives of both 1C and C1 conformations (Figs. 3 and 4). Those of the C1 type are considerably the more stimulating. The hydroxyl groups attached to C3 and C4, inclined 19 degrees above and 19 degrees below the adjacent plane of the molecule, appear to be necessary for the critical linkage at the receptor site. Lack of effects by metabolic inhibitors (azide, fluoride, iodoacetate, etc.) or of temperature effects upon the initial excitatory process, suggests that this step depends upon specific physical rather than chemical reactions.

The nature of other polyol receptor sites and the molecular basis for genetic and species differences in taste capabilities remain largely unknown. Saccharin (*o*-sulfobenzime, Fig. 5) exemplifies both puzzles, since its molecule does not fit any known sugar receptor site, yet it is confused with sugar stimuli by humans and other primates, but probably not by nonprimate animals. The substitution of other groups for one hydrogen (dotted lines in Fig. 5) renders saccharin tasteless. The genetic basis of taste has been studied with phenylthiocarbamide (PTC). A strong bitter taste of PTC depends upon the chemical components indicated by dotted lines in Fig. 6, and upon possession of a dominant "taster" gene in humans. Curiously, a small change in the molecule (Fig. 7) yields a product 250 to 300 times sweeter than sugar.

Taste receptors for water have been reported to occur on mouth parts of mammals and invertebrates. Specialized amino acid and amine receptors are found on the legs of many anthropoids. The mechanisms by which adequate stimuli initiate nerve impulses in these cells offer a rich field for further investigation. Some stimuli, especially long-chain hydrocarbons, are known to act in an opposing manner, i.e., by decreasing, rather than increasing, the output of receptor impulses. Their effects resemble the actions of narcotics. Some authorities suggest that taste sensation, as ultimately perceived, probably results from a complex coded pattern of augmented or depressed frequencies of nerve impulses, originating in the different cells of a heterogeneous population of taste receptors.

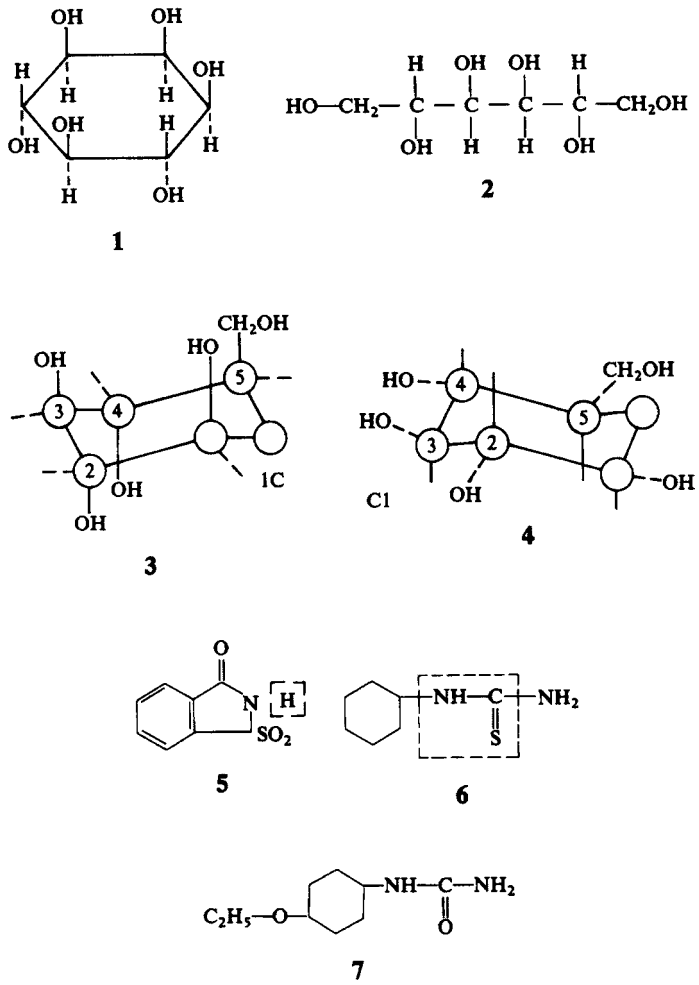

Fig. 1 through 7. Molecules illustrating relationships of seven different structures and their effects on taste receptors. (*After Hodgson*.)

Sense of Smell. For many years, physiologists have explained that the sense of smell is located in the mucus lining inside the nose. Traditionally, it has been observed that a person with a "dry" nose has little if any sense of smell. Molecules characteristic of certain flavorings must be moistened by the mucus before they can be detected. Traditionally, it also has been observed that these nerve cells (estimated to be a million or more) tend to become blocked (refuse further transmission of signals) upon prolonged exposure to any given odor. This blocking phenomenon can occur within just a few minutes after exposure to certain, usually powerful odors. When all is sorted out concerning the mechanics of tasting and smelling, it is highly likely that operationally the cells in the nose lining and the papillae of the tongue will be highly similar, if not identical — simply because many other interrelationships have been shown to be similar. Of course, over the years, some researchers have approached the phenomena of taste and odor separately. Some of the odor detection theories proposed have included: (1) the *vibrational theory* (Demerdach; Dyson; Wright); (2) the *stereochemical theory* (Amoore, Johnston, Naves); (3) the *theory of interfacial adsorption* (Beck; Davies); and the *profile functional group theory* (Beets).

The aforementioned theories are concerned with the size and shape of odorant molecules, but differ in certain underlying concepts. For example, accommodating for functional groups, electron donor-acceptor characteristics, as well as the sorptive nature of odorants on sensor sites. The vibration theory largely concentrates on the far-infrared and Raman spectral characteristics of odoriferous substances. The remaining theories concentrate on structural and behavior characteristics of odorant molecules, stressing direct interactions physically, chemically, and biologically with the olfactory sensor system.

The vibrational theory stresses so-called osmic frequencies (Wright) as setting up resonances in the sensory organs. In commenting on this concept, Dravnieks observed that spectra are codes describing molecular structures and shapes with emphasis on the distribution of atomic masses, distances,

and bond polarities. Questions regarding corresponding intra-molecular vibrations as direct factors in odor discrimination are independent of the validity of the spectral code.

In connection with the stereochemical theory, Amoore, although emphasizing the importance of molecular shape and size, also gives important emphasis to such chemical factors as electrophilic-nucleophilic characteristics, rotational moment, and the presence of functional groups. In the theory, the functional groups play a more important role in small molecules than in larger ones. Size and shape similarities were analyzed and demonstrated by preparing silhouettes patterned from three-dimensional molecular models.

Critics of the Amoore theory point out that electrophysiological data do not support the concept that sensors are sensitive to size and shape. Other authorities, however, point out that molecular size and shape, operating with a reactive character, most likely are odor relevant, but that this is not explained satisfactorily by the Amoore theory. Another objection to the theory is that equal weight is given to positive and negative differences in odorant molecules. Further, it is observed that the theory does not account for odor blocking or fatiguing (*anosmia*).

The profile functional group theory is a relatively complex two-step concept. First, it is visualized that the functional groups of the odorant molecule interact with the receptor site, thus causing a given orientation of the molecule. This, in turn, determines the final odor-relevant profile. Any similarity in profile at the receptor site causes similar signal transmissions to the brain. Because some adorant molecules will react more strongly at receptor sites than others, stronger signals will be transmitted.

The interfacial adsorption theory proposes that the orientation of odorant molecules is dependent upon their behavior at the hydrophilic-hydrophobic interface, taking into account interaction with the mucus and adjacent olfactory membrane.

Flavor Enhancers and Potentiators

A *flavor enhancer* is a substance that when present in a food accentuates the taste of the food without contributing any flavor of its own. This is reminiscent of the role of a catalyst in a chemical reaction, which promotes a reaction without chemically participating in the reaction. Although not usually regarded as a flavor enhancer, common salt, if not used excessively, enhances the taste of food substances. Salt does not fully meet the definition of an enhancer, however, because the salt is detectable as salt unless added in very minute quantities.

Monosodium glutamate for many years has been the best known and most widely used of the flavor enhancers. MSG is normally effective in concentrations of a relatively few parts per thousand, but far less powerful than the more recently developed flavor potentiators. Like enhancers, *potentiators* do not add any taste of their own to food substances, but intensify the taste response to the flavorings already present in the food. Because a potentiator is more powerful, smaller quantities of the substances are required than in the case of the enhancers.

The chronology of MSG commenced centuries ago when certain seaweeds were used in the Far East to improve the flavor of soups and certain other foods. It was not until 1908, however, that the curiosity of K. Ikeda (University of Tokyo) caused him to study the seaweed *Laminaria japonica*, traditionally used by Japanese cooks to enhance food flavoring. After much research on the seaweed, MSG was isolated and identified as an excellent flavor enhancer, particularly for high-protein foods. As an aside, it is interesting to note that Ritthausen in Germany had isolated glutamic acid as early as 1866 and his associates had prepared the sodium salt of the acid, namely monosodium glutamate. But the path of research in Germany was targeted in other directions; the flavor enhancing qualities of MSG were left to Ikeda to determine.

The Japanese throughout the first half of this century produced glutamic acid by extraction from natural materials, a slow, costly method. But, as the demand for MSG grew, cost tended to be a secondary factor. It was not until 1956 that Japanese microbiologists succeeded in developing the first industrial production of L-glutamic acid by means of fermentation. The problem of producing glutamic acid, as well as a number of other important amino acids, by fermentation was the lack of suitable strains of microorganisms for starting the cultures.

Initially, the Japanese researchers were successful in isolating microbial strains from natural sources that possessed good abilities to excrete and accumulate a large amount of the amino acid in the cultural broth, but only under very carefully controlled conditions. After much experimentation, a large-scale MSG production was achieved by the fermentation route. Sugar beets are now the most common raw material used.

Although listed as a GRAS substance for many years, questions concerning the safe usage of MSG have arisen from time to time and MSG still remains somewhat controversial. It is known that overconsumption of MSG can produce an illness, usually of just a few hours duration, in some persons. This is commonly referred to as the "Chinese Restaurant Syndrome" and is described in the entry on **Foodborne Diseases**. The possible seriousness of any deleterious effects of MSG tend to be countered by the many years the substance has been used by thousands of food processors and millions of chefs and home food preparers.

The 5′-Nucleotides. Also dating back many years in the Far East is the knowledge that Bonita tuna possesses a substance that very effectively enhances the flavor of foods. However, it was not until 1913 that S. Kodama (University of Tokyo) commenced a serious investigation directed toward identifying and isolating the substance from tuna. Initially, Kodama believed that the substance was the histidine salt of 5′-inosinic acid, but later found that the substance was actually 5′-inosinic acid itself. This nucleotide was found to be many more times as effective as MSG. Further research has shown that these nucleotides are present in many natural foods, including numerous species of fishes, beef, pork, and chicken.

The nucleotides, in addition to their effectiveness at much lower concentration, have been found to be superior to MSG for certain types of foods over and beyond those of a high-protein nature. It also has been observed that the nucleotides tend to create a sense of increased viscosity, providing more body, for example, to soups. Japanese manufacturers are now producing a series of the nucleotides by the enzymatic hydrolysis of ribonucleic acid. As of the early 1980s, these compounds are enjoying a high volume of production and consumption. It should be pointed out that the nucleotides are frequently used along with MSG. Some researchers point out that while the nucleotides and MSG have a lot in common, there is a considerable difference in their application. The nucleotides are up to 100 times more effective than MSG on a weight basis. Whereas MSG has been a favorite of processors for the enhancement of "meaty flavor," the range of the nucleotides is broader, modifying salty or sweet flavors and suppressing many undesirable flavors. The nucleotides are not a replacement for MSG. The substances do have a synergistic effect when used together. Generally, 1 gram of nucleotide used with 50 grams of MSG will have the same flavor intensifying result as 100 grams of MSG alone.

Because the market is so large, research continues at a good pace in seeking other potentiators. Established since the early 1940s, *maltol* is effectively used in foods that are high in carbohydrates, such as beverages, jams, and gelatins. Claims of reducing sugar content by 15% in products using maltol have been made. Other potentiators include dioctyl sodium sulfosuccinate, *N*,*N*′-di-*o*-tolylethylenediamine, and cyclamic acid.

FLAX *(Linum usitatissimum; Linaceae).* Flax is the name given to the pericycle fibers of *Linum usitatissimum*, a plant native to Europe. They were probably the first vegetable fibers to be used by man. Picture-writings at Thebes not only show the plant, but also give details of the processes used in making cloth from the fibers. Egyptians, Greeks, ancient Hebrews, and Romans knew the fiber and used it. Mummy cloths are often of linen.

The flax plant is a slender annual attaining 4 feet (1.2 meter) in height and branching slightly. It has small lanceolate leaves and clear blue flowers. When mature it bears seed capsules containing ten seeds each and about $\frac{1}{4}$inch (6.3 millimeters) in diameter. Successful cultivation demands an abundance of potassium and phosphorus in the soil and plenty of moisture. The plant is cultivated not only for the fibers, but also for oil. The best fibers are obtained from plants grown in cool regions, while the best oil is derived from plants grown in tropical countries like India. See Fig. 1.

For preparing flax, the plants are pulled or cut before they are mature, and stripped of all leaves and seed capsules. The denuded stems are then tied in small bunches and immersed either in stagnant or slowly running soft water, where they are left for several days. During this time, the stems are attacked by bacteria, which brings about fermentation, causing a breaking down of the woody tissues and a partial separation of cells due to the action of the bacterial enzymes on the pectic substances binding the cells together. This process is called "retting." Sometimes the flax stems are spread on the ground in a thin layer and left exposed to the action of dew and sunshine for a few weeks. The same result is obtained, the process being now called "dew-retting." The retted stems are removed from the water, washed and cleaned of as much nonfibrous material as possible. This process is known as "Scutching." "Hackling" follows, and is a sort of combing which removes any remaining nonfibrous material. The fibers thus obtained are in reality bundles of cells, which occurred as pericycle fibers in the stem. Good fibers vary from 12–36 inches (0.3–0.9 meter) in length, while many shorter ones are obtained. Short and tangled fibers are called "tow." The fibers vary in color from yellowish to dirty gray, largely depending on the attention paid to the retting process. They are soft and flexible, capable of division into smaller bundles of fewer cells. They are very strong, each cell possessing a uniformly thick wall that surrounds the very slender central cavity or lumen.

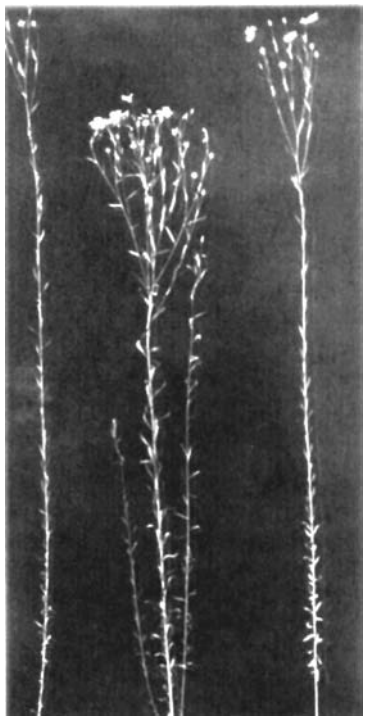

Fig. 1. Specimens of flax plant (*Linum usitatissimum*). Fiber flax is grown high (long stem), with no branches. High rate of planting causes this form of growth. Seed flax is planted at a lower rate of seeding, causing the plant to branch more and reach a lower height. (*USDA photo*.)

The principal use of the fibers is in the manufacture of thread requiring great strength, such as shoe thread, bookbinding thread, fish line and fish-net twine, and also in the making of fine cloth such as table-linen and handkerchief linen. All cloth made from flax fibers is called linen. Flax fibers conduct heat much more rapidly than cotton and so cloth made from them is cooler and much favored in tropical countries.

In addition to the fibers, flax plants yield a valuable oil, called linseed oil. The seeds are about 40% oil. In making this, the seeds are crushed by machinery, heated to 74 °C and treated with naphtha, which extracts the oil, or the oil is removed in a continuous screw press. This oil, a drying oil, is used in the manufacture of paints, varnishes, and patent leather, as well as in making linoleum and oilcloth.

The oil cake left after the oil is pressed from the seeds is used directly as a cattle food or is ground up into oil meal and used for the same purpose.

New Zealand Flax (Phormium tenax; Liliaceae). The fibers of this flax occur as schlerenchyma sheaths surrounding the vascular bundles in the long, straight, rather stiff leaves of the plant. The plant, a native of New Zealand, has been introduced into Australia and other countries. In the United States, it is cultivated to some extent, often as an ornamental plant. The leaves, from 4–8 feet (1.2–2.4 meters) long and up to 8 inches (20 centimeters) wide, may be 20% fibrous material. To obtain the fiber the leaves are cut off and scraped to remove much of the nonfibrous material. After this the fibers are combed out and cleaned. They are very white,

soft, flexible, lustrous and tough. They may be 5 feet (1.5 meters) long. The principal use of New Zealand flax is for binder twine, baling rope, and cordage, often in combination with sisal or other fibers. A fine cloth resembling linen duck can be woven from it.

FLEA-BEETLE *(Insecta, Coleoptra).* These insects are found on several crops, and they tend to be specialists. The *apple flea-beetle* (*Graptodera foliacea*) is tiny, about $\frac{1}{5}$-inch (5 millimeters) in length or less, of a brassy-green color, and is a leaf feeder. The species *Halticini* attacks beet, cabbage, horseradish, potato, and tomato. This beetle is small and of the jumping type. It attacks the leaves of the plant, producing large numbers of holes and ultimately destroying the leaves. The *grapevine flea-beetle* (*Graptodera chalybea*) is about $\frac{1}{4}$-inch (6 millimeters) in length, is of a blue metallic color, and feeds on buds and tender shoots of the vine in the spring. Treatment of these beetles is usually the application of chemicals to kill the grubs. Mechanical means of shaking the vine can also be effective, particularly for comparatively small plantings.

FLEA BITE. See **Dermatitis and Dermatosis**.

FLEA *(Insecta, Siphonaptera).* Small insects with transversely compressed bodies, sucking mouths, and no wings. See Fig. 1. They live as bloodsucking ectoparasites in the adult stage on the bodies of mammals and less frequently on birds. They progress chiefly by leaping. They have well-developed legs and possess great jumping ability (13 inches; 32.5 centimeters by some species in a single leap). The adults have short stout antennae and their mandibles are long and saw-toothed. The larvae have biting mouths and eat fragments of organic matter in the debris about the sleeping places of the hosts. The larvae are not parasitic. Stages in the development of the flea are egg, larva, pupa, and adult. The eggs are tiny, with a yellow coloration. An average flea is about $\frac{1}{8}$-inch (3 millimeters) long. Although fleas principally affect humans, dogs, cats, and rats, they also can be serious pests to poultry and other animals about the farm. In addition to their severe annoyance, fleas are carriers of serious diseases, the best known of which is the plague. Specific kinds of fleas include:

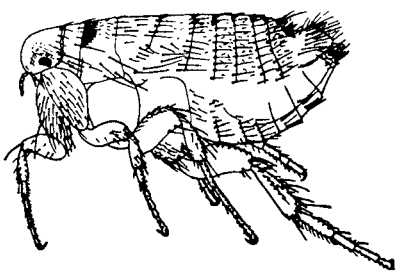

Fig. 1. Flea.

Human flea (Pulex irritans). Frequently bites around the legs and there may be 3 or 4 bites in a line. As contrasted with ticks and lice, fleas move from one host to the next. This flea also is found on hogs and commonly breeds in hog houses, as well as on dogs, cats, goats, domestic rats and some wild animals, such as skunks, coyotes, and badgers. This species is most often found in the Mississippi valley, in Texas, and westward to the Pacific Coast.

Dog flea (*Ctenocephalides canis*) and *cat flea* (*C. Felis*) are probably the most widespread of all fleas and will attack other animals and humans.

Northern rat flea (*Nosopsyllus* or *Ceratopsyllus fasciatus*, Bosc). This insect occurs in the northern United States and it is estimated that fleas of this species predominate on rats in that region (about 70%).

Sticktight flea (Echidnophaga gallinacea). This insect infests poultry and occasionally annoys humans and pets in the southern United States. Young chickens and other poultry are sometimes killed by heavy infestations.

Oriental rat flea (Xenopsylla cheopis). Although widely distributed throughout the United States, the insect is most abundant in southern California and the southern United States. In these regions, about half the fleas found on rats are of this species. The rat flea is capable of transmitting murine or endemic typhus from rats to humans. This disease, known as *Rickettsia typhi*, differs from Old World typhus. A very large percentage of the cases of this disease reported occur in the regions where the oriental rat flea is present. This species also serves as an intermediate for communicating dog tapeworm (*Dipylidium caninum*).

Chigoe flea (*Tunga* or *Dermatophilus penetrans*, Linne). A tiny, red-to-brown flea found in the West Indies, Mexico, and some of the southern United States. This insect, about $\frac{1}{25}$-inch (1 millimeter) in length, attacks humans, hogs, and domestic animals. Their habits and life cycle parallel those of other fleas, depending upon animal blood for their existence. They develop in the soil or in filthy debris. When abundant, this flea can be a severe pest to pigs and dairy animals. In humans, it tends to penetrate the body by way of the skin between toes and under fingernails, and the wound can be quite painful. The sore produced frequently becomes infected. The body of the flea must be removed with sterile instruments. When the female chigoe flea is full of eggs, she may be as large as a small pea. The chigoe flea must not be confused with the chigger, another small and annoying pest. See also **Chigger**.

FLEMING, SIR ALEXANDER (1881–1955). Alexander Fleming was a British bacteriologist, whose early study of penicillin won him the Nobel Prize for Physiology and Medicine in 1945, alongside Howard Florey and Ernst Chain.

Alexander was born in Lochfield, Scotland, to Hugh Fleming, an Ayrshire farmer, and his second wife, Grace. In 1901, he gained a scholarship to St Mary's Medical School, London. As a student, he came under the influence of Almroth Wright, Professor of Pathology and head of the Inoculation Department at St Mary's, the first research laboratory to be attached to a hospital in Britain. Together, Fleming and Wright were to constitute a productive research team and make several important discoveries in connection with the department's vaccine program. After Wright's retirement in 1946, Fleming became its director, and the department was renamed the Wright-Fleming Institute.

Their roles were often complementary. Wright carried out much of the intellectual work, while Fleming made significant contributions in the technical sphere. An early example of this teamwork was their investigation of war wounds carried out in the first wartime laboratory for medical research, set up in the Casino at Boulogne during World War I. This investigation led to two important conclusions: not only was the effectiveness of antiseptics then in common use reduced by several elements present in wounds, but antiseptics could even be harmful because they destroyed the patient's natural defense mechanism, the leucocytes.

This concern with the body's defense mechanism prepared Fleming for the discovery in 1922 of an enzyme present in mucus secretions, which dissolved bacteria, and which he considered to have a role in natural immunity. At Wright's suggestion, he called it "lysozyme". His discovery of penicillin occurred in a similar manner, as the result of a chance observation of bacterial inhibition on a culture plate. In 1928, whilst running experiments on staphylococci, he observed that the bacterial colonies on a plate contaminated by a mould, later identified as *Penicillium notatum* , appeared to have undergone lysis. He named the mold broth filtrate used in the experiments he devised to study its action, "penicillin". Although he recognized its potential use as a naturally occurring antiseptic, he advocated it mainly as a laboratory reagent for the isolation of the influenza bacillus, the suspected causal agent of flu, against which he had been trying to develop a vaccine. Nevertheless, some of the facts he established in his experiments were to form the basis of later studies of penicillin, including the work of the Oxford team 10 years after Fleming's discovery, which led to the development of penicillin as an antibiotic. See also **Chain, Ernst Boris (1906–1979)**; **Florey, Howard Walter (1898–1968)**; and **Penicillin (The History)**.

Fleming became aware of the Oxford work as a result of the 1940 article on penicillin published in the *Lancet* . Through his contact with a fellow member of the Ayrshire Society, Sir Andrew Duncan, then Minister of Supply, he was instrumental in stirring interest in the large-scale production of penicillin amongst British government circles.

His discovery was rewarded by the Nobel Prize, and by many other honors: a Knighthood, a Fellowship of the Royal Society and of the Royal College of Physicians, and honorary degrees from all over the world.

FLEXNER, SIMON (1863–1946). Simon Flexner was an American pathologist and first Director of the Rockefeller Institute for Medical Research.

Flexner studied medicine at the University of Louisville, graduating in 1889. The following year he went to the Johns Hopkins Hospital in Baltimore, to study pathology under William Henry Welch. There he was appointed to a number of different positions, rising to the professorship of pathological anatomy in 1898. Flexner was inspired in his researches by Welch, and later published a biography of his mentor.

Following a period as Professor of Pathology at the University of Pennsylvania, in 1903 Flexner was appointed Director of the new Rockefeller Institute for Medical Research in New York, a position he held until 1935. In this time he displayed considerable administrative skill, attracting a number of talented researchers to work at the Institute. Under his guidance the staff worked on many bacteriological problems, the solution of which had the potential to transform clinical medicine.

In 1905, during a severe epidemic of cerebrospinal meningitis, Flexner developed a serum and a novel method of administration which reduced the mortality of the disease. When an epidemic of poliomyelitis reached America in 1907, he and his colleagues studied the disease, and demonstrated that a filterable virus was responsible for the disease. This work laid the foundations for the eventual preparation of a vaccine forty years later. Flexner published widely on the pathology and bacteriology of many diseases, including bubonic plague, dysentery and encephalitis lethargica, and from 1904 edited the *Journal of Experimental Medicine* . See also **Bacteriology**; and **Bacteriology (The History)**.

CLAIRE E. J. HERRICK, London, UK

FLEXURE. Flexure is a term used to denote the curved or bent state of a loaded beam. A horizontally located beam, transversely loaded with vertically directed load, offers an example of load-carrying ability derived through flexure. In flexure, an elastic structural material undergoes a deflection sufficient to set up in its material stresses that will support the load. Deflection under load is an essential and necessary part of the process of load carrying by a beam, for until the deflection has occurred, there are set up in the beam no resisting forces. Thus, if an unloaded beam is perfectly straight and horizontal, it must assume a slightly curved position if any external load is supported by it. The only way in which a loaded beam could be straight would be to have had an initial deflection in a direction opposite to the loading.

The so-called ordinary, or common, flexure theory establishes a relation between the fiber stresses at any point in a beam and the bending moment causing these stresses. This theory is based on two fundamental assumptions. The first assumption is that a cross-section that was a plane before bending remains a plane after bending. This implies that the unit deformations are proportional to the distance from the neutral axis. The second assumption is that the fiber stresses are proportional to the deformations resulting from these stresses. If a tension member is subjected to an axial load in a testing machine, it will be found that, for stresses below the proportional limit, the ratio of the unit stress to the unit deformation is a constant called the modulus of elasticity. This would also be true if the test specimen were a short compression member. In order to reconcile the second assumption, it must be further assumed both that the fibers act similar to test specimens, and that the modulus of elasticity is the same for tension and compression.

It will now be shown how deflection and load-carrying ability are interrelated in a beam. See Fig. 1. First, it will be assumed that the structural material is elastic; that is, within the elastic limit the stress is proportional to the strain inducing it, and that it is a homogenous material.

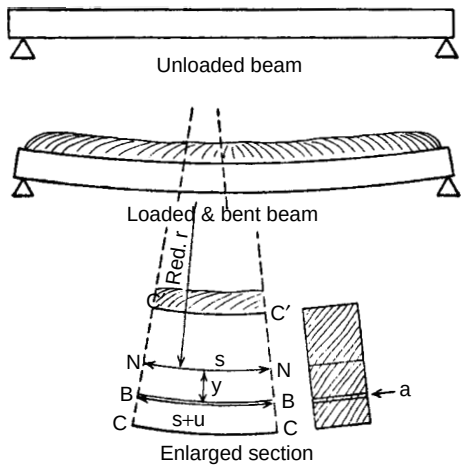

Fig. 1. Beam unloaded and in flexure.

The results produced by materials not exactly meeting these specifications are usually in good accord with the theory based on these assumptions.

Assume that there is a beam of rectangular cross-section mounted horizontally between simple supports. If one were further to assume this material is weightless, the axis of the beam would be absolutely horizontal. Next, a gravity load is placed on the beam, resulting in a certain deflection, which sets up resisting couples within the beam, enabling it to carry the load. It must be evident that, after a static condition is reached, the external bending moment thus imposed on the beam must, at any point, be balanced by an internal moment arising out of the stresses in the material of the beam. Next, consider the enlarged section of the bent beam. If the section is taken sufficiently small, it can be assumed to be bent in the arc of a circle whose radius is r. The upper fibers, i.e., $C'C'$, are naturally compressed or shortened in length, and the lower, CC, are stretched. At some intermediate plane, NN, there must exist an unstretched fiber whose length is the same as it possessed in the unloaded state. This axis of no strain is called the neutral axis. If its length is s, then the length of a typical fiber such as BB, located at a distance y from the neutral axis, is $s + u$, in which u represents the stretch, and u/s is the percentage stretch, or strain, of the material. From the geometry of the figure it is apparent that the strain $u/s = y/r$. Since stress is proportional to strain, and the factor of proportionality is the modulus of elasticity E, it follows that the stress on $BB = f = Ey/r$. Referring to the cross section of this small element of the beam, the end area of fiber BB is taken as a. The stress f acting on this area produces an elementary internal force of af. Above the neutral axis there are similarly produced forces, but oppositely directed. The sum of all these longitudinal forces is, of course, zero, since the beam is static; however, at any cross section they produce, *in toto*, a moment around the neutral axis that is exactly equal to the external bending moment at that section. For example, the moment of the force acting on the fiber BB is afy about the neutral axis. The total moment, then, is the Σafy about the neutral axis.

Substituting Ey/r for f the total moment equals

$$\frac{E}{r}\int ay^2 = \frac{E}{r}I$$

The last step shows how the moment of inertia enters into the flexure formula. Since r is not a convenient quantity to work with, a substitution of f/y is made for E/r, resulting in the common flexure formula:

$$f = \frac{My}{I}$$

In this formula, M is the bending moment at a section where the moment of inertia is I, and f is the unit stress at y distance from the neutral axis.

It is ready shown that the neutral axis is coincident with the centroid of the cross section of the beam. From the above, we extract the following equation:

$$af = \frac{E}{r}ay$$

$$\int af = \frac{E}{r}\int ay$$

$\int af$ is the total force within the beam parallel to the neutral axis, and is zero, as explained above, but this results also in $\int ay$ being equal to zero, which can be true only when the distance y is a moment arm around the center of gravity of the cross-sectional area.

The flexure formula is valid as long as the stresses are within the proportional limit and if the neutral axis is a principal axis. For oblique loading, a separate stress is found with respect to each of the two principal axes. These stresses are then combined. In the derivation of this formula it is assumed that the horizontal stresses are the only internal forces which resist the external bending. As a matter of fact, the true maximum tensile or compressive unit stress, called a principal stress, is the resultant of the bending and the shearing stress acting at the point. But, as has been previously stated, the stresses which are obtained by the flexure formula are reasonably correct for ordinary design purposes.

FLIGHT (Birds). See **Birds**.

FLIGHT DATA RECORDER. Regulatory agencies require airline aircraft to be equipped with a flight data recorder and a cockpit voice recorder. These devices record information that may be vital to the analysis of unusual and unexpected flight circumstances. Hence, these recorders must be protected to withstand severe environmental conditions, as may be encountered in accident survival. The flight data recorder is contained within a protective enclosure of heavy steel with successive layers of insulating and ablative materials. The housing is designed to exceed impacts of 100 g's and a fire of 2,000 °F (1093 °C) temperature for 30 minutes. The tape portion is designed to pass a 48-hour seawater immersion test. The housing also provides shielding against accidental erasure through short circuits or other random external electric current producing a magnetic field.

Variables recorded include: altitude, from −1,000 feet to +50,000 feet (−305 meters to +15,420 meters); air speed; heading recording, operated from the aircraft compass system through a synchro repeater recording to an accuracy of ±2°, with a system electrically independent of the recorder, i.e., powered from the same source as the compass to eliminate errors; vertical acceleration, with signal obtained from remotely mounted vertical accelerometers with recording accuracy of ±0.2 g; and a timing system which records at one-minute intervals on the edge of the recording medium. The accuracy of the timing system is not dependent on the tape speed or primary power frequency. Additional features include a channel to record aircraft pitch from the vertical gyro and circuitry to record marker beacon signals.

The recording medium used is high-tensile-strength stainless metal foil upon which the record is made by engraving a line approximately .001 inch (0.025 millimeter) in width. The foil can withstand severe accident environments without need for thermal, mechanical, or magnetic protection. The method of engraving prevents the record from appearing on the other side of the foil so that simultaneous recording on both sides of the foil may be made; or the tape may be turned over and used. The tape is contained in an easily replaceable magazine.

A separate cockpit voice recorder is of similar overall construction and records all voice communications between crew members on the flight deck; all voice communications transmitted or received by radio; and all voice communications on the aircraft intercom system. The recorder will preserve the last 30 minutes of the crew's voice communications to aid in accident investigation. The record amplifier, bias oscillator/mixer and monitor are packaged in subassemblies which plug into the main chassis. Assembly circuit boards are mounted on rugged structure, with point-to-point wiring (in contrast to printed wiring) used throughout. The magnetic tape used is stored in a quickly removable magazine, which fits within the protective enclosure and requires no threading or adjustment when installed. The tape is stored within the magazine as a continuous loop; no spools or reels are used. An associated microphone monitor system is mounted overhead in the cockpit to pick up crew members' voices.

FLIGHT ENVELOPE. Also called a V-n or a V-g diagram, indicates the relationship of limit load factors with corresponding aircraft speeds for ready reference and use by the aircraft stress analyst. See Fig. 1. The envelope represents in empirical form, data similar to those that might be obtained from accelerometer records made during definitive flight tests.

FLIGHT PATH. The flight path of any aircraft is the path in space described by the center of gravity of the aircraft.

FLINT. Flint is a rock composed essentially of a crypto-crystalline form of silica. It is very dense and tough, breaking with a conchoidal fracture; colors, usually dark grays, blues, or browns, often black. It occurs chiefly as nodules and masses in chalks and limestones. Flint is particularly interesting because it was used by primitive man for making instruments (artifacts) for thousands of years before he learned to use bone and metal. Flint remained an essential mineral resource for making fire, including the flint locks on guns, until the close of the eighteenth century. From the dawn of civilization, the best flint has come from Belgium and the coastal chalks of the English Channel and the Paris Basin. See also **Chert**.

FLINTY CRUSH-ROCK. A term proposed by the Scottish geologist Clough for the almost structureless, flinty portion of mylonite, an extreme product of dynamic metamorphism.

FLIP-FLOP. A bistable device, the output of which assumes one of two stable states, depending upon the state of the most recently applied input

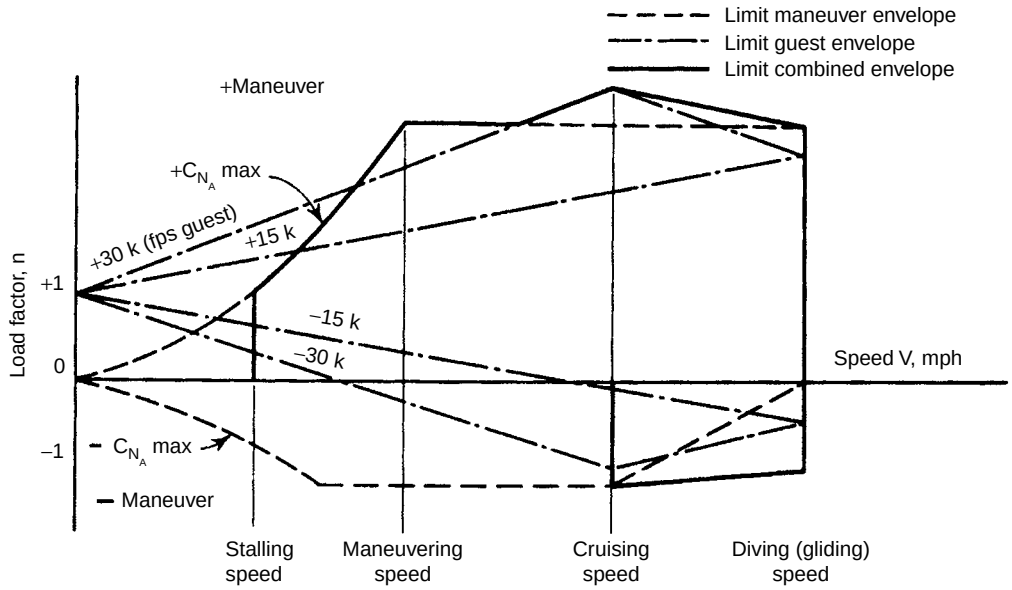

Fig. 1. Typical V-n diagram (flight envelope).

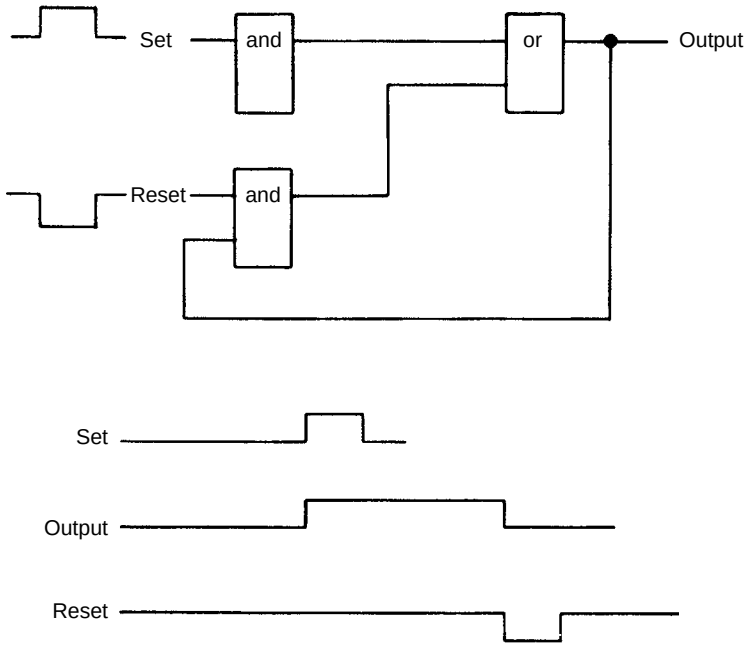

Fig. 1. Direct-coupled flip-flop or latch.

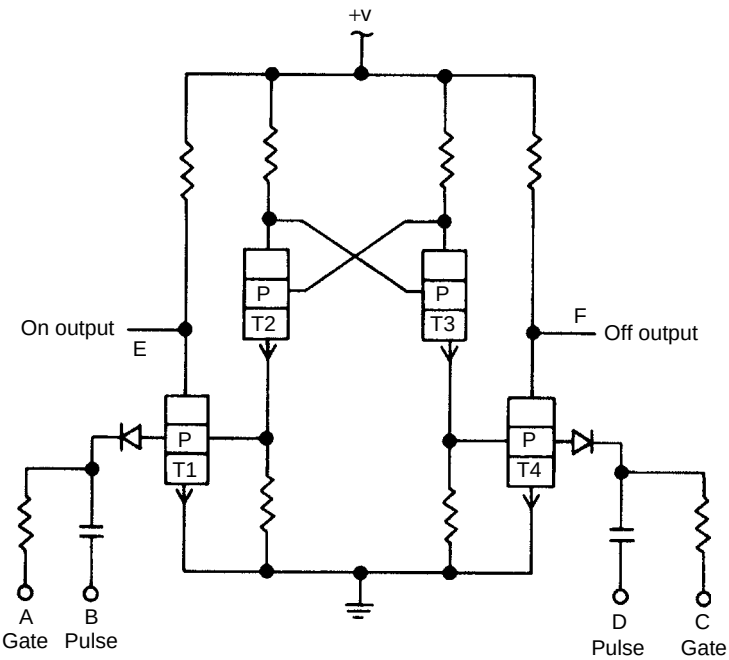

Fig. 2. Gated direct-coupled flip-flop.

signal. Also known as a toggle. The flip-flop in computer systems is used for storing information. A direct-coupled flip-flop or latch, constructed of AND and OR logical elements, is shown in Fig. 1. The output is fed back to the input. A set pulse initially turns on the output, and the output then provides its own input even though the set pulse is removed. The circuit remains "latched" in this condition until a reset pulse breaks the feedback loop.

A gated transistor flip-flop is shown in Fig. 2. When the flip-flop is in the "off" condition, transistor T_4 is "off" and the "off" output F is at $+V$. This represents a binary 1 state. Transistor T_1 is "on" and "on" output E is at 0 V. This represents a binary 0 state. Transistor T_3 is in a state of low conduction, and its emitter voltage is not sufficient to forward-bias T_4. Transistor T_2, however, is in a state of heavy conduction and its emitter voltage forward-biases T_1 and thus holds it "on." To change the output state of the flip-flop, a conditioning gate of 0 V is applied to input C while the signal on input D is still positive. Thus, when the set pulse at input D goes to 0 V, a negative shift appears at the emitter of T_3. T_3 instantly goes into heavy conduction. The reduced collector voltage causes T_2 to go into a state of low conduction. The voltage at the emitter of T_2 is reduced and biases T_1 "off." When the ac transient has receded, the T_3 emitter voltage holds T_4 "on." The flip-flop can be turned "off" by applying gate and pulse inputs to points A and B, respectively.

A flip-flop of this type may be connected for binary operation by connecting A to F and C to E, and by applying the input pulse to both B and D. Since the gate must be applied before the pulse arrives, the output alternately changes state whenever a pulse is applied. The circuit may be used to build a shift register by connecting the "off" output of the previous stage to gate C, connecting the "on" output of the previous stage to gate A, and applying a pulse to inputs B and D.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

FLIPPER. An appendage of the aquatic mammals in which the digits are enveloped by continuous tissue so that the entire structure forms a flat paddle for swimming. Flippers occur in seals, manatees, whales, and related forms.

FLOATERS. Floaters are particles that seem to be in front of the eye, but are actually floating in the vitreous humor, which is the transparent gel-like fluid that fills the inside cavity of the eyeball between the lens and the retina.

Floaters may be small flecks of protein or other matter that were trapped in the clear vitreous fluid during the formation of the eye prior to birth. As you mature, vitreous fluid deteriorates, which can also cause floaters to develop. The vitreous gel starts to thicken or shrink as middle-age approaches, forming clumps or strands inside the eye. The shrinking of the vitreous gel causes it to detach from the retina, and this pulling can cause small amounts of bleeding, which appear as floaters or flashes of light. It happens frequently in nearsighted people and those who have had cataract surgery. This posterior detachment, which causes floaters, also can occur in people who have had Yag laser eye surgery or who have had inflammation inside the eye. One can also get floaters from injuries to the eye, diseases of the eye, or crystal-like deposits that form in the vitreous, although these causes are not as common as other causes.

Floaters appear as different shapes to different people. They can look like small dots, circles, lines, clouds, or cobwebs. Some floaters appear to be strung together with a weblike thread. Floaters are actually shadows cast on the retina, the nerve layer at the back of the eye that senses light and allows you to see. Many people occasionally experience the sensation of spots floating in their field of vision, especially when looking at the sky or at a blank background. These spots usually come and go in very short order; but as you mature, the spots can appear more frequently.

Most floaters are harmless. However, they can also be symptomatic of serious retinal problems such as diabetic retinopathy or macular degeneration. These conditions can lead to a retinal tear or a retinal detachment, both of which are a more serious situation because either can lead to partial or complete loss of vision. Consult your eye doctor if spots or floaters suddenly increase in number or frequency. Also, if the spots appear fixed and do not move around when you move your head or eyes, they may be a sign of macular degeneration and should be checked.

A symptom that sometimes accompanies floaters is flashes. Flashes are bright spots of light that burst into the visual field when eyelids are closed. They are usually comprised of tiny dashes that form either an oval or a circle, somewhat like a sparkler in a dark room. Flashes occur when the vitreous shrinks and pulls on the retina, causing retina cells to fire and create the perception of light flashes.

Floaters are generally not treated but there are ways to cope with the inconvenience. Moving the eye around when a floater appears in the line of vision will help get rid of it. Eye movement causes the fluid inside the eye to shift allowing the floater to move out of the way. Looking up and down, as opposed to from side to side, may be a more effective means of removing floaters from the line of sight. Floaters sometimes fade over time and become less bothersome.

If floaters are caused by a retinal tear, the tear must be repaired as soon as possible before it leads to retinal detachment and serious vision loss. A retinal tear can usually be successfully treated by a laser that tacks the tear back in place. A simple, virtually painless procedure performed in an ophthalmologist's office.

Vision Rx, Inc., Elmsford, NY

FLOATING AMPLIFIER. Also known as an isolated amplifier, the design does not require that the input and output signals be referred to the same signal reference point (ground). Generally, differential-input amplifiers meet this definition. However, the term *floating* normally excludes an amplifier where the input reference point and the output reference point are common, that is, either through a signal conductor or a power supply. Specifically, floating amplifier refers to an amplifier that includes a four-terminal coupling device, such as light-coupled signal-transmission element or a transformer.

The most common floating amplifier used in digital-data acquisition and instrumentation systems is the carrier amplifier. See also **Carrier Amplifier**. The input signal is coupled to the output amplifier, demodulated, and filtered to produce an output signal. As shown in Fig. 1, there may be feedback from the output to the input by means of a similar modulator-demodulator combination.

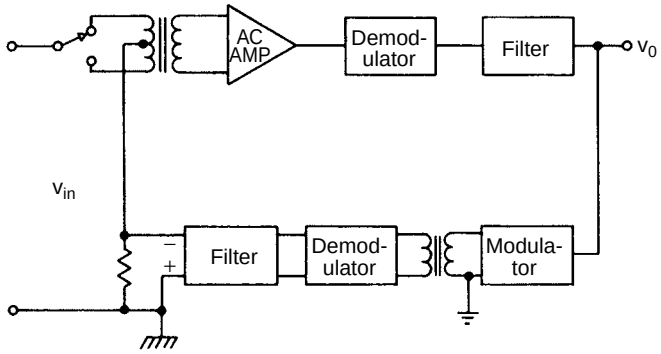

Fig. 1. Floating-carrier amplifier with feedback.

The four-terminal isolation property of the transformer provides complete isolation of the amplifier input and output, in that the signal reference point (ground) for the input may be completely independent of the output-signal reference point. Thus, even though the preamplifier and postamplifier may be single-ended, the amplifier performs as a differential amplifier. The breakdown-voltage limitation of the transformer determines the maximum difference in the ground potential between the input and output circuits. Normally, this is quite high (hundreds of volts). Thus, this amplifier design is particularly well adapted to uses that require the amplification of signals in the presence of high common-mode voltages. Several commercial designs are available.

The achievement of a high common-mode rejection ratio is made difficult in the design of these amplifiers because of the unbalanced nature of the preamplifier and unbalances in the coupling transformer. Typically used for these designs are well-shielded transformers with low interwinding capacitances. Also, if optimum performance is to be achieved, the guard-shielding technique usually is needed.

As compared with other differential-amplifier techniques, the isolated carrier amplifier is relatively expensive. A primary advantage is the input/output isolation. A major disadvantage is a reasonably narrow band-width (normally less than 10 kHz), imposed by carrier-frequency limitations and by transformer characteristics. If the guard shield is not correctly connected to the source of common-mode voltage, the ac common-mode rejection ratio frequency is markedly degraded. In summary, where optimum performance is to be achieved, the design is restricted to three-wire systems.

THOMAS J. HARRISON, IBM Corporation, Boca Raton, FL

FLOATING CONTROLLER. An automatic controller in which the control action provides a predetermined relation between the deviation and the rate of travel of the final controlling element. The final controlling element moves relatively slow toward either one or the other of its two extreme positions, depending on whether the controlled variable is above or below the setpoint. The output of the controller can remain at any value in its operating range when the actuating error signal is zero and constant. Hence, the output is said to float. Types of floating control action include:

Single Speed Floating Control. The final controlling element moves at a single rate regardless of the amount of deviation. A single-contact on-off controller can produce single speed floating action if used with a slow-running reversible electric motor driven valve. When the temperature, for example, is at or above the setpoint, the valve will run toward its closed position at a single speed. When the temperature is below the contact setting, the valve will run toward its open position at the same single speed.

Usually a *neutral zone* is used in connection with single speed floating control. When the value of the controlled variable is in the neutral zone between contact setting, no contact is made and the valve remains motionless. It is possible for this form of control to produce a nearly exact correlation for any load condition.

Multispeed Floating Control. In this system, the final controlling element is moved at two or more rates, each rate corresponding to a definite range of values of deviation.

Proportional Speed Floating Control. In this system, the position of the final controlling element is changed at a rate that is proportional to deviation. The greater the deviation, the faster the movement of the valve.

See also **Control Action**.

FLOATING-POINT ARITHMETIC. A method of calculation that automatically accounts for the location of the radix point. This is usually accomplished by handling the number as a signed mantissa times the radix raised to an integral exponent; e.g., the decimal number +88.3 might be written as $+.883 \times 10^2$; the binary number $-.0001$ as $-.11 \times 2^{-2}$. See **Fixed-Point Arithmetic**.

FLOCCULATING AGENTS. Flocculation is defined as the process by which fine particles, suspended in a liquid medium, form stable aggregates called flocs. The degree of flocculation can be defined mathematically as the number of particles in a system before flocculation divided by the number of particles (flocs) after flocculation. Flocculation makes the suspension nonhomogeneous on a macroscopic scale. A complete or partial separation of the solid from the liquid phase can then be made by using a number of different mechanical devices. Flocculating agents are chemical additives which, at relatively low levels compared to the weight of the solid phase, increase the degree of flocculation of a suspension. They act on a molecular level on the surfaces of the particles to reduce repulsive forces and increase attractive forces.

Applications

The principal use of flocculating agents is to aid in making solid–liquid separations. These applications include:

1. Removing small amounts of suspended inorganic or organic particles from surface water prior to its use as drinking water or industrial process water.
2. Concentrating the organic solids in municipal or industrial wastewater to produce a sludge with a minimum volume and water content for incineration or other means of disposal, and a clarified (very low suspended solids) water that can be discharged or recycled. This operation is often called dewatering.
3. Removing suspended inorganic material from waste streams generated in the beneficiation of ores or nonmetallic minerals, to form a concentrated slurry that can be used for reclamation of mined out areas or other uses and a clarified water that can be discharged or recycled.
4. Separating the solid and liquid phases in leaching operations, where a valuable material is contained in the liquid phase, so its recovery is to be maximized.
5. Binding fine cellulose fibers and solid inorganic additives to long cellulose fibers as the paper pulp is being formed into sheets on a paper machine. See also **Papermaking and Finishing**.

Chemical Composition

Flocculants can be classified as inorganic or organic. The inorganic group as well as some highly charged cationic organic flocculants are sometimes referred to as coagulants; however, no such distinction is made in this article.

Inorganic Flocculating Agents. The inorganic flocculating agents are water-soluble salts of divalent or trivalent metals. For all practical purposes these metals are aluminum, iron, and calcium. The principal materials currently in use are: aluminum sulfate [CAS: 10043-01-3], aluminum chloride hydroxide [CAS: 1327-41-9], sodium aluminate [CAS: 1302-42-7], ferric chloride [CAS: 7705-08-0], ferric sulfate [CAS: 10028-22-5], ferrous sulfate [CAS: 7720-78-7], calcium hydroxide [CAS: 1305-62-0], and lime [CAS: 1305-78-8].

Organic Flocculants. The organic flocculants are all water-soluble natural or synthetic polymers. Since the 1950s the use of natural products as flocculating agents as steadily declined as more effective synthetics have taken their place. The only natural polymers used to a significant degree as flocculants are starch [CAS: 9005-25-8] and guar gum [CAS: 9000-30-0]. Examples of synthetic polymers include acrylamide–acrylic polymers and their derivatives, polyamines and their derivatives, poly(ethylene oxide), and allylamine polymers.

Mechanism of Flocculation

In order to form flocs the individual particles must move and collide. Flocculation can be classified as either orthokinetic or perikinetic. In the first case particle motion results from turbulence in the suspension, and in the latter from Brownian motion. Orthokinetic motion is almost always the case in industrial applications. At very close distances, polar materials are attracted by dipole-induced dipole interactions commonly called van der Waals forces. In most aqueous suspensions, ionization of surface groups gives the particle an overall negative charge. The charged particles in suspension are surrounded by a group of positive ions referred to as the double layer. As particles approach each other the resulting electrostatic repulsion of the double layers prevents flocculation. Increasing the ionic strength of the liquid medium reduces the repulsion until the particles start to aggregate at the critical flocculation concentration. As the charge of these positive ions forming the double layer is increased by adding higher charged ions to the system, the double layer gets nearer to the surface allowing the particles to become closer and be attracted by the van der Waals forces. This is the explanation for the empirically derived Schulze-Hardy rule that the critical flocculation concentration of positive ions for a particular system decreases proportionally with the sixth power of the charge. This mechanism is called double-layer compression and is often cited for the inorganic flocculating agents, such as alum and ferric salts, which add trivalent ions to the system. However, this explanation of the action of aluminum and ferric salts does not take into account the fact that they are present at least partially as polymeric species when added to many systems, and that polymeric precipitates may be formed at the usual concentrations and the pH range that they are used.

The second flocculation mechanism is referred to as the charge patch or electrostatic mechanism. A highly cationic polymer is adsorbed on a negative particle surface in a flat conformation. This promotes flocculation by first reducing the overall negative charge on the particle thus reducing interparticle repulsion. A third mechanism is called bridging. Some individual segments of a very high molecular weight polymer, usually a high molecular weight anionic polyacrylamide, adsorb on a surface. Large segments of the polymer extend into the liquid phase where other segments are adsorbed on other particles, effectively linking the particles together with polymer bridges. In contrast to the first two mechanisms, bridging is strongly affected by molecular weight and the ionic content of the solution.

A fourth mechanism is called sweep flocculation. It is used primarily in very low solids systems such as raw water clarification. Addition of an inorganic salt produces a metal hydroxide precipitate which entrains fine particles of other suspended solids as it settles.

Flocculant Performance and Selection

There is no comprehensive quantitative theory for predicting flocculation behavior that can be used for flocculant selection. This must ultimately be determined experimentally. There are three variables that affect the results obtained in any particular flocculation system. These are the type of flocculant, type of substrate, and type of mechanical treatment of the flocculated substrate. The size and physical properties of the flocs that form, rather than the degree of flocculation, are the key elements in determining the practical effectiveness of a flocculant in any specific application. The effect of mechanical treatment can be viewed in terms of the type of force applied to the flocs. In thickeners and settling basins the flocs are acted on by gravity and by the weight of material added on top of them. In vacuum filters the flocs are subjected to atmospheric pressure. In belt presses and plate-and-frame filters the flocs are subjected to mechanical pressure and in centrifuges they are subject to centrifugal forces. In a flowing system, such as a continuous paper machine, they are subjected to shear and elongational forces on the same scale as the particle size. In addition to the type of force that is applied to the flocs, the kinetics of floc formation also plays an important role in the results obtained in their application.

There are some general principles that can serve as guidelines for initial screening in terms of both flocculant chemistry and molecular weight. In general the large flocs formed by high molecular weight polymers tend to settle faster than smaller ones.

In the case of thickeners, the process of compaction of the flocculated material is important. The flocs settle to the bottom and gradually coalesce under the weight of the material on top of them. As the bed of flocculated material compacts, water is released. Usually the bed is slowly stirred with a rotating rake to release trapped water. The concentrated slurry, called the

underflow, is pumped out the bottom. Compaction can often be promoted by mixing coarse material with the substrate because it creates channels for the upward flow of water as it falls through the bed of flocculated material. The amount of compaction is critical in terms of calculating the size of the thickener needed for a particular operation. The process of compaction has been extensively reviewed in the literature.

For most substrates the operating dosage of flocculant necessary to give the settling rate necessary to operate a thickener is well below the maximum amount that can be adsorbed on the substrate. As more and more polymer is added above this operating dosage the flocs can become larger and somewhat sticky. The bed of flocculated material then becomes very viscous. The rake mechanism may become overloaded and the flocculated material may not flow into the underflow pump. The dosage response and the sensitivity to overdosing may affect the selection of flocculating agent.

For filter belt presses and centrifuges, resistance to shear and mechanical pressure is the most important parameter. In general, flocs produced by charge patch neutralization are stronger than those produced by inorganic salts alone.

For vacuum filters, both the rate of filtration and the dryness of the cake may be important. The filter cake can be modeled as a porous solid, and the best flocculants are the ones that can keep the pores open.

Retention aid polymers are used in a very high shear environment, so floc strength and the ability for flocs to reform after being sheared is important. The optimum floc size is a compromise. Larger flocs give better free drainage, but tend to produce an uneven sheet owing to air breakthrough in the suction portions of the paper machine. In some cases the type of floc needed for retention can be seen as similar to that needed for vacuum filtration. Floc size can be controlled by both the type of flocculant and the addition point.

General guidelines concerning the initial selection of flocculant chemistry are *(1)* suspensions of organic materials, such as municipal waste, are usually treated with a cationic flocculant, either inorganic or organic; and *(2)* suspensions of inorganic materials such as clay are usually treated with an anionic polymer or a combination of an anionic polymer with a cationic flocculating agent.

Operating Parameters and Control

Flocculating agents differ from other materials used in the chemical process industries in that their effect not only depends on the amount added, but also on the concentration of the solution and the point at which it is added. The process streams to which flocculants are added often vary in composition over relatively short time periods. This presents special problems in process control.

Dilution. In many applications, dilution of the flocculant solution before it is mixed with the substrate stream can improve performance. The mechanism probably involves getting a more uniform distribution of the polymer molecules.

Addition Point. The flocculant addition point in a continuous system can also have a significant effect on flocculant performance.

Automatic Control. In some industries, the waste streams can vary in composition over a relatively short time period. When the solids level of a slurry changes, the entire dosage response may change. Automatic systems are available for thickeners that adjust the dosage according to the incoming solids level, overflow turbidity, and streaming current potential.

Toxicology and Environmental Issues

Based on animal studies and mutagenicity studies, trace amounts of organic polymers do not appear to present a toxicity problem in drinking water. The reaction products with both chlorine and ozone also appear to have low toxicity. The principal concern is the presence of unreacted monomer and other toxic and potentially carcinogenic nonpolymeric organic compounds in commercial polymeric flocculants. The principal compounds are acrylamide in acrylamide based polymers, dimethyldiallyammonium chloride in allylic polymers, and epichlorohydrin and chlorinated propanols in polyamines, as well as the reaction products of these compounds with ozone and chlorine.

Until 1990 the EPA maintained a list of chemicals suitable for potable water treatment in the United States. Since then the entire question of certification and standards has been turned over to a group of organizations headed by the National Sanitation Foundation, which has issued voluntary standards. As of January 1992, standards had been issued for most of the principal inorganic products, but only for three polymers, poly(DADMAC), Epi-DMA (epichlorohydrindimethylamine) polymers and polyacrylamide. Certifications for commercial products meeting specified standards are issued by the National Sanitation Foundation, Underwriter Laboratories, and Safe Water Additives Institute (SWAI).

The same questions about the safety of organic flocculants have been raised in other countries. The most drastic response has occurred in Japan and Switzerland where the use of any synthetic polymers for drinking water treatment is not permitted.

FLOOD. See **Earth**; **Fronts and Storms**; **Hydrology**; and **Wetlands**.

FLOODPLAIN. The term *floodplain* has a range of physically and ecologically based definitions, in addition to a regulatory (i.e., flood control) definition. From the physical perspective, floodplains are a component of the dimensions and geometry of river channels, which as a whole reflect the runoff and sediment load they carry. Floodplains have been defined as the relatively level surface, or surfaces within a river valley, caused by the depositional work of the river, especially during flood or high-water. Nanson and Croke define floodplains more precisely as "the largely horizontally-bedded alluvial landform adjacent to a channel, separated from the channel by banks, and built of sediment transported by the present flow-regime." They identify lateral point bar accretion, overbank vertical accretion, and braid-channel accretion as the dominant floodplain forming processes in their genetic floodplain classification based on stream power and sediment texture. Figure 1 is a conceptual diagram of a natural river basin that identifies the valley floor, floodplain, river corridor, and channel areas of a basin. Floodplains and riparian areas immediately adjacent to active channels have been documented as very important in sediment retention during high flows. Floodplains also act to dissipate bed shear stress and attenuate flood peaks contained in the primary channel. In addition, flood peaks travel downstream faster when a river corridor becomes confined laterally from its floodplain. Floodplains provide important aquatic and terrestrial habitat in addition to significant hydrologic, water quality, and aesthetic benefits.

The biological and ecological importance of floodplains has been well documented. Many species of aquatic organisms require floodplains to complete stages of their life history, including reproduction, rearing, and hibernation. Floodplains also provide important refugia for aquatic organisms during episodes of high flow or vulnerability to predators. Aquatic invertebrates and fish seek refuge from high bed shear stresses and flow velocities during floods in the hydraulically rough, slow-moving areas beyond the margins of the active channel and on the floodplain. The

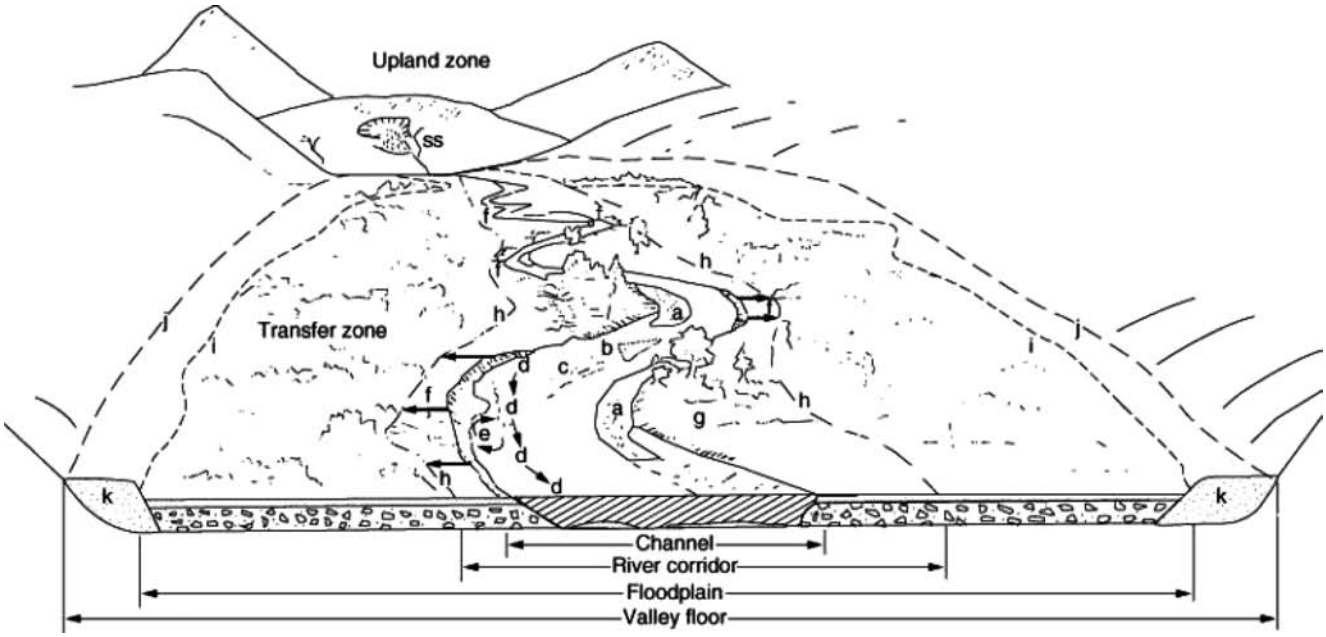

Fig. 1. Generalized valley floor, floodplain, river corridor, and channel orientation (from Brookes and Shields Ref.). Letters refer to channel corridor characteristics: (a) point bar, (b) midchannel bar, (c) riffle, (d) pool, (e) secondary current, (f) bank erosion, (g) riparian vegetation, (h) corridor boundary, (i) floodplain boundary, (j) valley floor boundary, (k) terrace, (ss) sediment supply and storage zone

importance of these floodplain functions has been shown in population growth simulation models that predict increases in biomass of fish and aquatic invertebrates with increases in floodplain width. Floodplains have been recognized as critical elements of healthy river ecosystems. Without a connected and functioning floodplain, a river corridor ecosystem is incomplete. In their work on the flood pulse concept, Junk et al. describe an aquatic–terrestrial transition zone that moves across the floodplain as flood waters rise. This moving transitional zone is essential to the successful recruitment, establishment, and growth of many species of vegetation, fish, and other organisms in river corridor ecosystems. Historically, floods were often viewed as destructive disturbances to floodplain ecosystems. More recently, however, the prevention of floods has been viewed as the more destructive disturbance to floodplain ecosystems.

The regulatory definition of floodplains originated because valley floors and floodplains have historically been attractive sites for human settlement. For thousands of years, humans have built civilizations along river corridors. In fact, the very "cradle of civilization" was built near the confluence of the Tigris and Euphrates Rivers in what is now southern Iraq. Most human development along river corridors has been established on floodplains. Floodplains are naturally flat, close to water, and have fertile soils, making them ideal for agriculture, building sites, and industry location. Therefore, a regulatory floodplain is a surface next to a channel that is inundated once during a given return period. Regulatory floodplains may or may not be related to physical floodplains. In most cases, some form of flood protection is provided on regulatory floodplains. The administration of regulatory floodplains differs from country to country. In the United States, Congress established the National Flood Insurance Program (NFIP) with the passage of the National Flood Insurance Act of 1968 to identify regulatory floodplains and administer flood protection. The Federal Emergency Management Agency (FEMA) currently administers the NFIP. In return for federally subsidized insurance, communities with access to the NFIP must adopt and enforce a floodplain management ordinance to reduce future flood risks to new construction in Special Flood Hazard Areas (SFHAs). A SFHA is an area within the 100-year floodplain (note this is not a physical reality, but rather a regulatory designation that is discussed in more detail below). Development may take place within a SFHA, provided that development complies with local floodplain management ordinances, which must meet the minimum federal requirements. Communities that participate in the NFIP must implement floodplain management measures in the development of their floodplain lands. FEMA expects these measures to constitute an overall community program of corrective and preventive measures for reducing future flood damage. In general, floodplain management measures address zoning, subdivision, or building requirements for structures in the floodplain and special-purpose floodplain ordinances.

The 100-year flood (and floodplain) was selected by an expert panel as the standard for protection within the NFIP. The 100-year flood (or the 1% annual-chance flood) was chosen on the basis that it provides a higher level of protection (FEMA does not specify what "higher" refers to) while not imposing overly stringent requirements or the burden of excessive costs on property owners. Flood Insurance Studies (FIS), which apply detailed hydrologic and hydraulic analyses, have been performed for many of the watersheds in the United States that are currently included in the NFIP. The results of these analyses include flood insurance rate maps (FIRMs) that identify areas of flood risk and, perhaps most importantly, the boundaries of the regulatory 100-year floodway. The regulatory floodway is defined as the channel of a stream plus any adjacent floodplain areas that must be kept free of encroachment so that the entire base flood (100-year flood) discharge can be conveyed with no greater than a 1.0-foot increase in the base flood elevation. See also **Floods**.

FLOODS. The interface between humans and hydrologic features across Earth's surface has helped shape human culture. From the earliest agricultural, complex societies established along some of the great rivers of the world to the bustling seaports of today, humans have gained from the myriad advantages of living in proximity to water. Fertile soil, ease of transportation, and availability of resources (both materials and energy) have allowed for the development of complex material and intellectual cultures. The relationship between water and humans also brings a great deal of risk. Flooding is one of these risks. The impact of floods on humans has been evident from *Genesis* to tonight's evening news. Early Mesopotamian maps may have been drawn to facilitate the reestablishment of property lines after flooding. While the impacts of flooding on humans have been positive in the case of fertile floodplains that support much of the world's agricultural productivity, there is the potential for a great deal of negative impact [Brown, 1984; Clark et al., 1985]. Losses of life and property have focused the efforts of scientists, engineers, and government agencies on the prediction, control, and mitigation of floods and flood damage.

Definition

Streams are linear water features that flow under the impetus of gravity. The amount of water contained in a stream is usually regulated by contributions of groundwater and surface runoff to the stream channel [Zaslavsky and Sinai, 1981; Knighton, 1998]. Much of the time water in a stream flows within the confines of its channel. When inputs of water increase sufficiently, stream discharge leaves the stream channel and covers all or parts of the adjacent floodplain. Since the floodplain surface is usually a virtually flat surface and near the elevation of the stream channel, water can easily spread over the floodplain once water exceeds the elevation of the stream's banks. Most floods develop over a period of days or months as discharge increases gradually [Hirschboeck, 1987, 1988]. Flash floods by contrast occur suddenly with little warning and are of short duration. Semiarid and arid areas are likely to experience flash floods [Reid and Frostick, 1987; Hassan, 1990]. Flooding is not always associated directly with stream channels. Flooding occurs any time when water covers a surface that is normally not under water. Flooding can occur in coastal areas, low lying areas with poor drainage, or locations with inadequate urban drainage systems.

Factors that Lead to Flooding

Floods have a multitude of causes. Some causes are related to what would be considered natural processes that would occur whether humans are present or not. Many causes have been affected by human activities. In some cases the severity of floods and the types of damage are a direct result of agriculture, urbanization, and the areas selected for development. In all cases flooding is related to increased discharge in stream channels.

Saturated Soil. Much of Earth's surface is covered by a weathered cover of regolith. Whether forming a true soil with well-developed horizons or a weakly developed detrital cover, the regolith is composed of a mix of mineral particles, organic fragments, and pore space. Commonly, much of the pore space is filled with air and to a lesser extent water. When large amounts of precipitation are received in a region, the pore space fills with water as the input of water from precipitation exceeds the output of water from the soil column to the water table. Decreases in infiltration lead to increases in runoff. The lag time between the precipitation event and the arrival of water to stream channels decreases significantly when soil saturation occurs.

Basin Characteristics. Surface characteristics influence infiltration and runoff rates. Impervious surfaces such as exposed bedrock or a paved road accelerate surface runoff, thus decreasing lag time between the precipitation event and entrance of water into a nearby channel. Urbanized areas, therefore, with large percentages of impervious surface such as roofs, streets, and parking lots coupled with an engineered drainage system designed to move water quickly to stream channels greatly increase the chances that some flooding will occur after a significant precipitation event. Conversely, rural areas with large areas of soil, natural vegetation, and the potential for a faster infiltration rate are less likely to have significant flooding resulting from a single precipitation event.

Topography. Topography will influence the rate at which precipitation will be incorporated as stream discharge [Patton, 1988]. Steep, rocky canyon walls have low infiltration rates as well as a great deal of potential gravitational energy that leads to the concentration of discharge during a short period of time. Alluvial plains usually have a much longer lag time between a precipitation event and the introduction of runoff water into a stream channel. When land cover on steeper slopes is affected by perturbations such as wild fire or building-related oversteepening of slopes, the likelihood of mass movement events is greatly increased. These events are usually related to unstable regolith on steep slopes, which is susceptible to failure when sufficient precipitation is received.

High Amounts of Precipitation. Flooding is created by the delivery of larger than normal amounts of runoff into stream channels [Smith and Ward, 1998]. Periods of above-average precipitation lead to floods. In some cases seasonal variability leads to great fluctuations in stream discharge. Wet–dry subtropical or monsoonal climates with distinctive seasons of precipitation lead to fluctuations from dry stream channels to potential flooding events. These cyclical events are related to large-scale atmospheric circulation patterns that operate through an annual or longer period. In the midlatitudes, the annual migration of subtropical high pressures and the polar front lead to distinct precipitation patterns. In the tropics, monsoonal flow can lead to large precipitation events. On longer time scales El Niño and La Niña events are persistent over several years and can lead to wet or dry conditions over large areas of Earth's surface from the Equator to the midlatitudes. See also **El Niño**; and **La Niña**.

Extended Wet Periods. In many cases flooding is caused by the reception of precipitation over an extended time period, on the order of weeks to months, that leads to the saturation of soils in a large-scale region. This saturation leads to increased runoff at a time when streams are at capacity. Additional water introduced to stream channels cannot be conveyed in the channel but is spread across the floodplain. Wet periods are related to synoptic conditions such as the position of the polar front that delivers cyclonic storms in quick succession. See also **Floodplain**.

Decaying Tropical Cyclones. Some of the largest precipitation amounts received as the result of a single meteorological event have been associated with the movement of tropical cyclones (e.g., hurricanes, cyclones, and typhoons) poleward and over continents. These powerful cyclonic storms carry large amounts of warm moist air over land surfaces. While wind speeds associated with these storms decrease quickly after landfall, these decaying storms are capable of delivering precipitation over wide areas during a relatively short period of time, on the order of days to weeks. In some cases cyclonic storms associated with the polar front may exacerbate conditions by introducing a lifting mechanism that leads to increased condensation and precipitation. The relatively low-lying coastal plain of eastern North America is especially susceptible to damage from these types of storms.

Intense Thunderstorms

Thunderstorms are usually intense, short-lived storms that produce high winds, hail, and heavy rainfall. These storms can be caused by convection in moist tropical air masses over continental surfaces or fast-moving cold fronts that displace those moist air masses. When these storms develop over mountainous areas where the precipitation is concentrated by the topography the potential for large, catastrophic floods is great. The eastern slope of the Rocky Mountains and the southwestern deserts of North America are common locations for the development of thunderstorms. As moist air encounters higher elevations in these locations, it is forced to rise.

Unstable atmospheric conditions are created as mountain slopes heat and in turn heat the atmosphere. Adiabatic cooling causes condensation and the development of large cumulonimbus clouds that can reach the upper altitudes of the troposphere. Sometimes there is little movement associated with a thunderstorm or thunderstorm complex, with respect to the ground; heavy precipitation concentrated in a small geographical area can have catastrophic results.

Quick Snowmelt

The storage of water in the form of snow temporarily removes that water from the hydrologic cycle. In many cases this sequestration of water is short term. Snow accumulates during winter especially at higher elevations and latitudes. With the onset of warmer spring and summer conditions, snowmelt supplies water to streams. A typical early warming may mean that snowmelt may be accelerated with large amounts of runoff entering stream channels. Mountain ranges in mid-latitude coastal regions such as the Coast Ranges and Sierra Nevada of California receive a significant portion of their annual precipitation in the form of snow. It is possible for warm early spring rains to fall on the snowpack, causing much faster runoff than normal. Another source of snowmelt is the subsurface introduction of heat from volcanic activity. Large volcanoes can be high enough to support permanent snow and ice cover. High temperatures associated with volcanic activity lead to the instantaneous melting of snow and ice. The melt water is commonly mixed with pyroclastic debris to form lahars [Smith, 1996].

Failure of Flood Control Structures

A variety of humanly constructed structures are used in an effort to limit the extent and severity of flooding. Dams and levees are common flood control structures designed to contain water within designated areas. However, these structures can fail because of construction errors, poor design, and overtopping by water. Flood control structures can fail because of the failure of a key component. For example, a spillway that erodes away has the potential to lead to the catastrophic failure of the entire dam as the water cuts downward. Sound structures may fail when the water retained by the structure exceeds the height of the structure. Large precipitation events or the displacement of water in a reservoir have the potential to send water flowing over the flood control structure which, could lead to the failure of the structure through erosion. Flooding may be exacerbated by these structures since a feature such as a levee tends to raise the stream level well above the floodplain. When a levee fails, a large amount of fluvial energy is concentrated through that break and a great deal of damage can occur near the break.

Cyclonic Storm Created Surges

In low-lying coastal locations a temporary increase in sea level associated with the approach and landfall of storms with significantly high winds and low central pressure can cause significant damage. Sea level rises in response to low pressure as it passes over ocean surfaces. Additionally, the upper portion of the water column is pushed into waves by the high winds. Storm surges can be more than 5 m above the normal high tide [Rappaport, 1994]. Barrier islands are also susceptible to flooding by storm surges. Development on barrier islands along the southeastern coast of North America has led to rising property damage related to storms. See also **Cyclones**; and **Hurricanes**.

Mass Movement Events

A variety of mass movement events, while strictly not fluvial events, behave in a similar way to floods. The gravitationally fueled downhill movement of poorly consolidated regolith results from the introduction of meteoric water that adds weight and decreases hillslope cohesion. These events can do significant damage. Several types of mass movement events are composed of a larger percentage of sediments than a typical stream. Events such as mudflows, or lahars, commonly may approach the viscosity and velocity of streams. Valleys can be filled with fine-grained sediments as the deposits dewater following the initial surge of water and sediment. A variety of factors lead to mass movement events. The removal of plant cover by fire may expose soil surfaces so that infiltration rates may increase and lead to the accumulation of water along failure planes in the regolith. In areas with a subtropical wet–dry climate, such as the Mediterranean climate type, the burning of plant cover during the dry season and a subsequent wet season before the reestablishment of plant cover leads to mass wasting events. See also **Earth**; and **Monsoon**.

Flood Defenses, Planning, and Management

In western countries, rivers prone to flooding are often carefully managed. Defenses such as levees, bunds, reservoirs, and weirs are used to prevent rivers from bursting their banks. Coastal flooding has been addressed in Europe with costal defenses, such as sea walls and beach nourishment.

- London is protected from flooding by a huge mechanical barrier across the River Thames at Woolwich Reach, which is raised when the water level reaches a certain point. The Thames Barrier is the world's second largest movable flood barrier after the Oosterscheldekering (Eastern Scheldt storm surge barrier) in the Netherlands. The Thames Barrier is built across a 523 m (1,716 ft) wide stretch of the river; the barrier divides the river into six navigable and four smaller non-navigable channels between nine large concrete piers. The flood gates across the openings are radial, i.e., half-cylindrical, and they operate by rotating, raised by hydraulics out of a horizontal sill below the water to form the barrier. They can rotate further to allow for 'underspill' for maintenance. All the gates are made of steel. The four large central gates are 61 meters (200 ft) long, 10.5 meters (34.5 ft) high (above local ground level) and weigh 1,500 tons (metric) (1,476 tons); the outer two gates are 31.5 meters (103 ft). Additionally, four radial gates by the riverbanks can be lowered. These gate openings, unlike the main six, are non-navigable. The barrier was designed to cope with sea level rises until around 2030. In 2005, a suggestion that it might become necessary to supersede the Thames Barrier with a much more ambitious ten-mile-long barrier across the Thames Estuary from Sheerness in Kent to Southend in Essex was made public.
- Venice has a similar arrangement, although it is already unable to cope with very high tides, and will become increasingly inadequate if anticipated rises in sea level occur.
- The biggest and most elaborate flood defenses can be found in the Netherlands, where they are referred to as Delta Works with the Oosterscheldedam as its crowning achievement. These works were built in response to the North Sea flood of 1953 off the south western part of the Netherlands. The Dutch had already built one of worlds largest dams in the north: the Afsluitdijk in response to a flooding in 1916.

In some flood-prone areas with high population density, such as parts of the Netherlands, England, and New Orleans and the Mississippi River Delta, planning laws have been used to prevent building on flood plains. In some cases, pressure from developers has caused these controls to be eroded, with an increasing number of new developments reliant on artificial defenses for protection from floodwaters.

Bangladesh has not experienced catastrophic coastal flooding since 1995, but the country relies heavily on foreign support and technology to combat flooding. The United States has donated hurricane shelters to the country, and India provides the Bangladesh government with weather forecasting to give the country time to plan its response to hurricanes.

Significant Modern Floods

Although nature is normally blamed for the damage, the people are at least partly responsible for the presence of human activities in areas prone to the hazard of floods. Prevention is often aimed at containing floods with defenses, often increasing the potential damage in the long run. Nowadays, strategies to deal with floods more and more include evacuation strategies to avert damage.

Significant floods from 1889-2005 include:

- Johnstown Flood disaster (or *Great Flood of 1889*), May 31, 1889. Heavy rains and the failure of the South Fork Dam near Johnstown, Pennsylvania released 20-million gallons of water, causing the death of over 2,200 people and $17 million (USD) in damage. It was the first major disaster relief effort handled by the new American Red Cross, led by Clara Barton. Support for victims came from all over the United States and 18 foreign countries. It remains one of the greatest disasters in U.S. history.
- On September 8, 1900, a storm surge associated with an unnamed hurricane killed between 6,000 and 8,000 people in Galveston, Texas.
- The storm early January 1916 in the Zuiderzee caused severe damage along the coast of Noord-Holland, Utrecht, Gelderland, Overijssel and Friesland in the Netherlands.

- The 1916 Clermont flood caused 61 deaths in central Queensland due to a small but intense cyclone.
- The Great Mississippi Flood in 1927 was one of the most destructive floods in United States history.
- The 1931 Huang He flood along the Yangtze River caused between 800,000 and 4,000,000 deaths in China, one of a series of disastrous floods on the Huang He.
- The North Sea Flood of 1953 caused over 2,000 deaths in the Dutch province of Zeeland and the United Kingdom and led to the construction of the Delta Works and the Thames Barrier.
- In 1954 flood rains in Teheran, Iran, resulted in some 10,000 deaths.
- The Hunter Valley floods of 1955 in New South Wales destroyed over 100 homes and caused 45,000 to be evacuated.
- In 1957, storm surge flooding from Hurricane Audrey killed about 400 people in southwest Louisiana.
- On October 9, 1963 a landslide into the Vaiont Dam caused a flood which killed over 2,000 people.
- In 1965 Hurricane Betsy flooded large areas of New Orleans drowning around 40 people.
- On January 18-26, 1969 floods and mudslides from heavy rains in Southern California caused widespread property damage; at least 100 deaths. Another downpour (Feb. 23–26) caused further floods and mudslides; at least 18 dead.
- In 1971 heavy rains severely flooded the Red River Delta, Hanoi, North Vietnam, killing over 100,000 people.
- In 1972 Hurricane Agnes caused 122 deaths, mostly from the overflowing of rivers in New York and Pennsylvania.
- In 1975 Typhoon Nina destroyed over sixty dams in China's Henan Province, killing an estimated 80,000 to 200,000 people from floods and subsequent famine. The Chinese government never acknowledged this event.
- On August 1, 1976 a flash flood along Route 34 in Big Thompson Canyon, Loveland CO., left 139 dead.
- On Sunday, November 6, 1977, around 1:30 am the Kelly Barnes Dam, located above Toccoa Falls Bible College near Toccoa, Georgia, USA fails, killing 39.
- In 1982 the river Jucar (Valencia, Spain) broke Tous's reservoir provoking an avalanche of 16.000 m3/seg., and more than 30 dead men. The flood was called "La pantanada".
- In August 1988, the heaviest monsoon in 70 years inundated three-fourths of Bangladesh, killing more than 1,300 and leaving 30 million homeless. Damage estimated at over $1 billion.
- The Great Flood of 1993 was one of the most destructive floods in United States history. Two months of heavy rain caused the Mississippi River and tributaries to flood; 50 deaths and about $12 billion in damage. Almost 70,000 left homeless.
- The Red River Flood of 1997 was a major flood that occurred in April and May 1997, along the Red River of the North in North Dakota, South Dakota and Minnesota. It was the most severe flood of the river since 1826. Torrential rains and snowmelt in January 1997 produced severe floods in parts of California, Oregon, Washington, Idaho, Nevada, and Montana, causing 36 deaths and about $2–3 billion in damage. In March flooding and tornadoes plagued Arkansas, Missouri, Mississippi, Tennessee, Illinois, Indiana, Kentucky, Ohio, and West Virginia. 67 were killed and damage totaled approximately $1 billion.
- In 1999 heavy rains in Northern Venezuela caused catastrophic flooding and mudslides, killing an estimated 5,000 to 20,000 people. Devastating floods in Vietnam caused $285 million in damage and killed more than 700 people. Torrential downpours and flooding in S. Korea, China, Japan, the Philippines, and Thailand left more than 950 dead and millions homeless.
- The 2000 Mozambique flood, caused by heavy rains followed by a cyclone, covered much of the country for three weeks, killing thousands, leaving the country devastated for years afterwards.
- In June 2001, floods from Tropical Storm Allison killed over 30 people in the Houston area.
- The 2002 European flood was a flooding disaster that affected many countries including Czech Republic, Germany and Poland. Historical cities like Prague and Dresden were partly flooded. In Germany the so called "Jahrhundertflut" (flood of century) caused 22.6 billion Euro (27.19 billion U.S. Dollars) in damage.
- In 2004 the Dominican Republic and Haiti were hit with torrential rains which caused the Soliel River to overflow, causing floods and mudslides, destroying villages, and killing more than 2,000. In South Asia annual monsoons left 5 million homeless and more than 1,800 dead in India, Nepal, and Bangladesh.
- One of Canada's most devastating floods happened in southern Alberta, Canada in June 2005. The flooding affected many major metropolitan areas including Calgary. After 3 weeks of flooding, 72 people died.
- In July of 2005 a record rainfall event of 37 inches in a 24-hour period and a week of monsoon rains left over 1,000 dead in Mumbai, India.
- In August 2005 Hurricane Katrina was the costliest and one of the deadliest hurricanes in American history. It is possible that Katrina was the largest hurricane of its strength to approach the United States in recorded history; its sheer size caused devastation many miles from the center. The storm surge caused major or catastrophic damage along the coastlines of Louisiana, Mississippi, and Alabama, including the cities of Mobile, Alabama, Biloxi and Gulfport, Mississippi, and Slidell, Louisiana. Levees separating Lake Pontchartrain from New Orleans, Louisiana were breached by the surge, ultimately flooding roughly 80% of the city and many areas of neighboring parishes. Severe wind damage was reported well inland. Katrina is estimated to be responsible for $165 billion (2005 US dollars) in damages, making it the costliest hurricane in U.S. history. The storm has killed at least 1,604 people, making it the deadliest U.S. hurricane since the 1928 Okeechobee Hurricane.

Conclusion

Floods are generally caused by the combination of large amounts of precipitation and basin topography. For example, saturation of soils caused by large amounts of precipitation can lead to flooding. Urbanization of a drainage basin increases the amount of runoff reaching a channel and decreases the lag time between a precipitation event and peak flow. A variety of weather events lead to flooding, including extended wet periods, decaying tropical cyclones, intense thunderstorms, and quick snowmelt. In some cases humanly constructed structures designed to prevent flooding collapse, causing flooding or accentuating flooding. In low-lying coastal areas storm surges may cause significant flooding. Mass movement events are similar to flooding, although the proportion of sediments to water is larger than an alluvial flood with the outcome just as disastrous.

Humans respond to flooding in a variety of ways. Broadly defined these fall into two categories, structural and nonstructural measures. Structural measures include dams and dikes. Through time the efficacy of structural features has been questioned, and there has been a shift from purely structural approaches to controlling floods to a mix of structural and nonstructural flood mitigation strategies. Nonstructural measures include flood insurance, floodplain mapping, and land-use ordinances, acquisition and relocation, flood proofing, detection and response warning systems, soil bioengineering, and combined structural and nonstructural measures to reduce flood losses. Some progress is being made in addressing the hazards associated with flooding. The reduction of flood impacts continues at great expense, but vulnerability will continue to rise as long as more people build in floodplains, increasing the risk of catastrophic floods. Even the best warnings will not eliminate the risks increasingly being taken around the globe.

FLOOR BEAM. A beam that is the direct support of the floor load of a building and transfers this load to the adjacent girders or columns is a floor beam or floor joist. These beams are commonly of steel, reinforced or precast concrete, or wood.

The term floor beam is also used to designate the transverse beams of the floor system of a bridge which transmit load to the longitudinal girders or trusses.

FLOREY, HOWARD WALTER (1898–1968). Howard Florey was an Australian pathologist who in 1945 shared the Nobel Prize for Medicine with Alexander Fleming and Ernst Chain for developing penicillin.

Florey was born in Adelaide of Joseph Florey, who left England for Australia in the 1880s, and Bertha Wadham, a second generation Australian. Joseph was a successful boot and shoe manufacturer in Adelaide. However, when Howard was 15, his father's business ran into difficulties, and it was clear that he would have to become self-reliant. This may have influenced his outlook in later life, when he showed great talent not only as a scientist, but also as an entrepreneur, obtaining funding for the many research projects he planned and directed, such as the penicillin project.

Florey attended Medical School in Adelaide, where he gained a Rhodes Scholarship to Magdalen College, Oxford, in 1922. He began research under the physiologist Sir Charles Sherrington, who encouraged him to apply for a studentship in pathology at Cambridge. It was there that he obtained his PhD on the physiological and pathological aspects of the circulation of blood and lymph in 1927, and was appointed Lecturer in Special Pathology. See also **Sherrington, Charles Scott (1857–1952)**.

In 1932, he applied for his first Chair, and was elected to the Professorship of Pathology at Sheffield. He reorganized the laboratories of four hospitals, was responsible for the teaching of pathology, and for a vast program of research. He was soon regarded as Britain's leading experimental pathologist, and was in a strong position to apply for the Chair of Pathology at Oxford. He took up the position at the Sir William Dunn School of Pathology in 1935, and was to stay there until 1962.

Florey transformed the School of Pathology by placing a new emphasis on research. His strategy consisted in directing several projects simultaneously, and in choosing researchers who could tackle different aspects of the research. However, he needed to devote considerable energy to making frequent applications for funding, which led him to describe himself as an "academic highway robber." Thanks to these applications, he was able to build a multidisciplinary group, which included the biochemists Ernst Chain and Norman Heatley, who were both to play an important part in the development of penicillin. See also **Chain, Ernst Boris (1906–1979)**.

The penicillin project, which was part of a wider program to study microorganisms with known antibacterial action, began in 1938. The funding Florey obtained from the Medical Research Council and the Rockefeller Foundation, the group he gathered around him, and the links he forged with neighboring departments, in particular the Dyson Perrins Laboratory of Organic Chemistry, created fruitful conditions for the study of the chemical and biological properties of penicillin. Furthermore, after 30 September 1939, the war provided a special focus for the experiments. These were designed to establish penicillin as a new kind of chemotherapeutic agent, both less toxic and more effective than the sulphonamide drugs, which were at the time the medical profession's favored weapon against wound infections. See also **Sulfonamides (The History)**.

The best known biological experiments were later referred to as the "mouse protection experiments." The first was carried out on 15 May 1940, when Florey infected eight mice with *Streptococcus*, and one hour later injected four of the mice with penicillin. The infection and treatment were administered by different routes, in the hope of demonstrating a true chemotherapeutic effect. The results were spectacular: the four untreated mice died after about 15 hours, while those treated with penicillin continued to live. Further experiments were carried out which demonstrated the effectiveness of penicillin against other bacteria, such as staphylococcus, pneumococcus, and the clostridia of gas gangrene. The results of these early experiments were published in a first article in the *Lancet*, on 24 August 1940.

The next stage of the program consisted in stepping up production in order to test the substance in humans. Florey asked Charles Fletcher at the Radcliffe Infirmary in Oxford to identify suitable cases, while he turned the School of Pathology into a small-scale production plant. Heatley devised several pieces of apparatus, among them a continuous counter-current extractor that was to be used for the large-scale production of penicillin in industry. By January 1941 a small amount of material was available for the first small-scale clinical trial, described in another *Lancet* article, on 16 August 1941. See also **Antibiotics: Penicillins and Others**.

By the time the article appeared, Florey had left for America accompanied by Heatley, in order to explore the possibilities of producing penicillin on a large scale in a country not yet at war, but whose cooperation was being sought by the British government to sustain their war effort. Florey and Heatley made the rounds of American laboratories. While Heatley was left behind to assist Merck & Co. in their early attempts at manufacturing penicillin, Florey returned to England in September to make plans for large-scale clinical trials. In this, he was helped by several British pharmaceutical companies and by various government committees set up to increase the production of penicillin and run large-scale clinical trials.

Florey became personally involved in the trials that took place in North Africa and Sicily in 1943. He instituted a local form of treatment that

was compatible with the small amounts of penicillin available at the beginning, and was largely responsible for convincing the military and medical establishments of the superiority of penicillin in the treatment of war wounds. By D-Day, it had acquired the status of a wonder drug. See also **Drug Discovery (The History)**.

After the war, Florey's group, in particular the chemist Edward Abraham, who had joined Chain to work on the chemistry of penicillin, developed another antibiotic, cephalosporin. However, Florey's own research moved away from antibiotics. He returned to studying the vascular system and mucus secretion, and developed a new interest in degenerative diseases. But his contribution to post-war science involved more than research: as President of the Royal Society, he gave it vitality and a new sense of purpose; as Provost of Queen's, he contributed to a period of expansion that gave the college an international outlook. Although he had adapted remarkably well to English academic life, he retained close ties with his country of origin. When the National University was being built in Canberra, he became involved in the organization of the John Curtin School of Medical Research.

FLORIDA CURRENT. All the northward moving water from the Straits of Florida to a point off Cape Hatteras where the current ceases to follow the continental slope. It is one of the swiftest of ocean currents (flowing at a rate of 2 to 5 knots (2.3 to 5.6 mph). See **Ocean Currents**.

FLORY, PAUL JOHN (1910–1985). Flory, who was born in Illinois, was educated at Manchester College, Indiana, and Ohio State University, where he completed a PhD in physical chemistry in 1934. His subsequent career encompassed both industry and academia. He first worked at DuPont (1934–1938), then at the University of Cincinnati (1938–1940), Standard Oil (1940–1943), and the Goodyear Tire Company (1943–1948). He was Professor of Chemistry at Cornell University (1948–1957), before becoming Executive Director of the Mellon Institute in 1957. From 1961 until his retirement in 1975 he held a chair of chemistry at Stanford University.

Flory's research focused on polymer science, to which he was introduced by Wallace Carothers at DuPont. He used statistical mechanics to calculate the most probable distribution of molecular sizes in polymeric materials, and applied the formula to produce a theory of gel formation. During the war he developed the Flory–Huggins theory of the behavior of polymers in solution. He later introduced the Flory temperature, at which polymer properties can be measured. His long-term interest in rubber-like elasticity led to research on the elasticity of fibrous proteins.

In 1974 Flory's contributions to the field of macromolecular science were recognized by the award of the Nobel Prize for Chemistry. His publications include two influential books, *Principles of Polymer Chemistry* (1953) and *Statistical Mechanics of Chain Molecules* (1969), and a collection of *Selected Works* (1985). He was a leading advocate for human rights, and in his spare time enjoyed art museums, swimming and hiking.

FLOTATION. A method of separating minerals from waste rock or solids of different kinds by agitating the pulverized mixture of solids with water, oil, and special chemicals that cause preferential wetting of solid particles of certain types by the oil, while other kinds are not wet. The unwetted particles are carried to the surface by the air bubbles and thus separated from the wetted particles. A frothing agent is also used to stabilize the bubbles in the form of a froth that can be easily separated from the body of the liquid (froth flotation). Do not confuse with floatation.

FLOUNDER. See **Fishes**.

FLOWAGE (Rock). This term, as used by geologists, signifies the internal movement of clays and rocks when stressed beyond the elastic limit. Important types of flowage are: granulation and foliation, although the latter is primarily a physical-chemical rather than a purely mechanical process, as in the other types of flowage.

FLOW CHART. A graphic representation of the major steps of work in a process. The illustrative symbols may represent documents, machines, or actions taken during the process. The area of concentration is on where a thing is to be done or who does it, rather than how it is to be done.

FLOW DIAGRAM. A graphical representation of a sequence of operations. In machine computation, a diagram with labeled boxes, arrows, etc., showing the logical pattern of a problem, but not ordinarily including machine commands.

FLOWER. That part of a plant involved in the sexual reproductive process of angiosperms. The formation of the flower is preliminary to the production of fruit with its seeds.

Flowers may be borne at the tip of a stem or a branch, in which case they are said to be terminal flowers. Or they may be borne in the axils of leaf primordia and called auxiliary. In very many plants the structure which subtends the flower does not develop into a leaf like the other leaves of the plant. Instead, it may remain very small and inconspicuous, or it may grow larger, but be of shape quite unlike that of an ordinary leaf. These structures which subtend flowers are called bracts. In a few plants the bracts are large and brilliantly colored, so that at times they are much more showy than are the flowers. The scarlet bracts of the *Poinsettia* and the white or pink bracts of the flowering dogwood are examples. See Fig. 1. In many monocotyledons, as Palms and Arums, there is a single large bract, which subtends and often more or less surrounds the flowers. Bracts of this kind are called spathes. The striped "pulpit" of the Jack-in-the-Pulpit and the white bract of the calla lily are well-known examples. The bract may surround and protect the flower in the bud.

Flowers may be borne singly or they may be associated in a cluster known as an inflorescence. See Fig. 2. A single flower is called a solitary flower, and the stalk that supports it is a peduncle. The stem that supports

Fig. 1. Blossom of flowering dogwood tree.

Fig. 2. Fragrant inflorescence of *Viburnum carlesi*, a flowering shrub, is sometimes called the pink snowball.

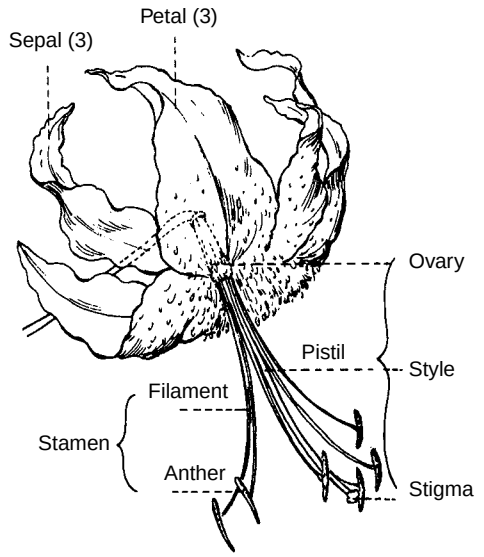

Fig. 3. Reproductive parts of a lily flower.

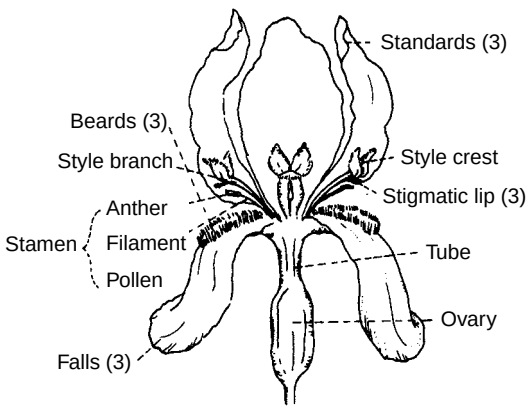

Fig. 4. Reproductive parts of an iris flower.

an inflorescence is also a peduncle, while the individual flowers of the inflorescence are supported on pedicels. When there is a distinct axis extending through an inflorescence, it is called a rachis. The arrangement of the flowers of an inflorescence varies in different groups. A common, and primitive, form of inflorescence is the raceme, in which the floral shoot grows at the apex and bears many pedicels, each ending in a single flower. The first flowers to open are those at the base of the raceme. If, in an inflorescence of this sort, each branch is a raceme bearing several flowers, it is called a panicle, or a compound raceme. If the flowers of the raceme are borne directly on the main axis, the inflorescence becomes a spike. A secondary spike, common in grasses, is a spikelet. A catkin is a spike that droops. A corymb is a modified raceme in which the lower pedicels of the inflorescence grow faster than the upper ones, so forming a more or less flattopped cluster. An umbel differs from a corymb in that it has no central rachis, all the pedicels of the inflorescence rising from a common point. More commonly umbels are compound, each of the main stalks of the inflorescence bearing an umbel at its tip. The inflorescence of the onion is an umbel, that of wild carrot a compound umbel. The inflorescence of the composite family is a head, which may be considered as an umbel in which the flowers are all sessile, without pedicels, on the apex of the stem. A cyme is an entirely different type of inflorescence. In the cyme the first flower to open is at the tip of the cluster. Below it on the stem are a number of bracts. From the axils of these bracts branches develop and they, too, end in a flower. This successive branching may be many times repeated, but always the flower terminates the stem and opens. Combinations of these types of inflorescences are found in many plants. A spadix is an inflorescence of the spike form with elongated axis, sessile flowers, and enveloping leaf, the spathe.

A flower consists of an axis, called the receptacle or torus; attached to the axis are the pistils, the stamens, the petals, and the sepals. See Figs. 3 and 4. The pistils and stamens are the essential organs of the flower, the petals and sepals are accessory organs. Any flower that has all four organs is a complete flower, while that which lacks one or more is incomplete. If the organs missing be either stamens or pistils, the flower is imperfect or unisexual. A perfect or bisexual flower has both sets of essential organs. If only the stamens are present, the flower is staminate; if only pistils, it is pistillate. If the two kinds of flowers, staminate and pistillate, are found on the same plant, that species of plant is monoecious. When the two unisexual flowers are found on different plants, the species is dioecious. Infrequently flowers are borne which lack both stamens and pistils, and are sterile. When the flower lacks sepals and petals, it is a naked flower.

Flowers may also be distinguished as regular and irregular. Regular flowers are those in which all the members of any set of organs are alike, forming a flower which is radially symmetrical or actinomorphic. Often the organs of one or more sets are not alike, forming an irregular flower. An irregular flower may be bilaterally symmetrical or zygomorphic, one half being a mirror image of the other.

The accessory floral organs, the sepals and petals together, constitute the perianth. In the complete flower, the perianth is composed of a whorl of sepals, which is called the calyx, and inside the calyx a whorl of petals called the corolla. The sepals are usually green and small. The function of the calyx seems to be to protect the other parts of the flower before the flower bud opens. The petals are usually thin and bright colored or white. The term corolla is applied to all the petals together. The corolla appears in a wide variety of shapes and colors. Its function seems to be to attract animals, especially insects, to the flower and so bring about pollination. The number of sepals and petals is constant for each species of plant. In the flowers of monocotyledons there are usually three of each, while in dicotyledons it varies from four to many, with five a very common number. As a further attraction to insects, many flowers possess special glands called nectaries which secrete a sweet fluid, nectar. Usually these nectaries are situated at the bases of the petals, though they may be found in many other places in the flower. Nectaries known as extrafloral nectaries are found on petioles of leaves or on the stipules.

The stamens, or microsporophylls, taken together constitute the androecium. Usually a stamen consists of two parts, a stalk or filament and an anther. The filament may be short and stout, or more commonly long

and slender, raising the anthers well above the base of the flower. The anther when first formed is an undifferentiated mass of cells. As it develops, four groups of cells become set off from the surrounding cells. In these masses, which usually appear as linear strands, certain cells undergo meiosis and become microspores. The sac containing them is therefore a microsporangium. A microspore develops into a pollen grain. The anther sac, or sporangium, when mature usually opens by two longitudinal slits, or by special pores, and frees the pollen grains. The number of stamens in a flower varies from one to many. Often there are vestigal stamens, or staminodia, present in the flower; in some plants these are large and brightly colored, in others they are small and inconspicuous.

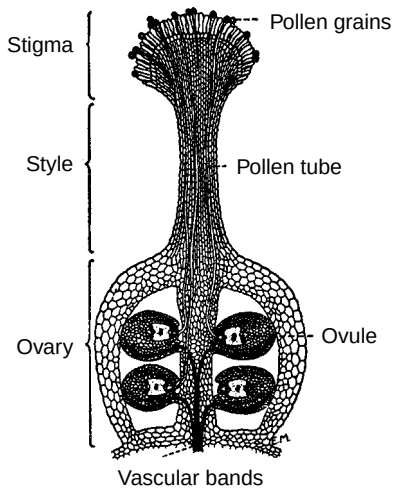

Fig. 5. Longitudinal section of flower pistil showing pollen tubes growing through the style and entering the ovules.

The pistil is the central organ of the flower. See Fig. 5. A single pistil or several pistils, which may be separate or partly, or even completely, united, is called a gynoecium. A pistil is composed of one or more modified leaves called carpels or megasporophylls. When there are two or more somewhat united carpels, the pistil is called compound. A pistil is composed of a basal ovary (ovulary), a terminal stigma, and usually an intermediate style, which is often long and slender. The stigma is a receptive organ, the surface of which is often either sticky or hairy. It is to the surface of the stigma that the pollen grains are carried when pollination takes place.

The style may be very much elongated to lift the stigma above the other parts of the flower and so increase the probability of pollination. The ovary has one or more cavities, or loculi. In these are located the ovules, which will become the seeds. The ovules are attached to the wall of the ovary or to a central column by a small stalk called the funiculus, through which the developing ovule receives nourishment. That region of the ovary to which the ovules are attached is called the placenta. The number of ovules in a single loculus varies from one to many.

Each ovule first appears as a minute rounded projection on the wall of the ovary or the columella. In the early period of its development, this projection consists of an undifferentiated mass of cells known as nucellar tissue. One or two layers of cells, known as the integuments, rise from the base of the projection and finally, almost completely surround the nucellar tissue. A minute opening through the integuments, called the micropyle, is left connecting the cavity of the ovary to the surface of the nucellar tissue. Within the nucellar tissue a very important series of cell divisions has taken place. While there are many variations of the process as it occurs in different species, the process is essentially as follows. Within the mass of nucellar tissue, a single cell has become differentiated from all the others by its larger size and denser cytoplasmic content. This is the megaspore mother cell. It divides twice in rapid succession to form a row of four cells. These two rapidly succeeding cell divisions take place in such a way that the four cells have the haploid or reduced number of chromosomes. The process is known as meiosis. Three of the four cells disintegrate and are lost. The fourth, or megaspore, is usually the one nearest the micropyle. It enlarges greatly, while by three successive divisions its nucleus divides to form eight nuclei, all contained within the wall of the very much enlarged female gametophyte, commonly called the embryo sac. The arrangement of these eight nuclei is quite uniform. In most plants, there are four of them at each end of the embryo sac. One from each end moves to the center of the embryo sac, where they form an intimate association and eventually fuse. These two are the polar nuclei. Of the three nuclei remaining at the micropylar end of the embryo sac, one becomes larger than the other two. This is the egg nucleus or megagamete; the other two form cells called the synergids. The three nuclei at the opposite end of the embryo sac form cells called the antipodals. The mature embryo sac is thus a seven-celled body, with seven nuclei.

The pollen grain is carried to the stigma by various agents. The pollen grains of different species of plants are very characteristically shaped, and are often strikingly beautiful of the many ridges or protuberances with which the outer wall is marked. At first, a pollen grain contains a single nucleus. This nucleus divides before leaving the anther and gives rise to two nuclei, one of them called the tube nucleus and the other the generative nucleus. The pollen grain germinates when it reaches the stigma, putting out a slender pollen tube, which grows down through the tissues of the style and into the ovary. In the pollen tube the generative nucleus divides to produce two sperm nuclei. There it grows toward an ovule, which it enters through the micropyle. The pollen tube continues to grow until its tip reaches the embryo sac, into which the two sperm nuclei are discharged. One of them fuses with the egg nucleus of the embryo sac, while the other passes to the polar nuclei and fuses with them. The nucleus formed by the fusion of these three nuclei is called the primary endosperm nucleus; it contains three times the haploid chromosome complement. The act of fusion of the male nucleus with the egg nucleus is called fertilization. From the endosperm nucleus there is formed by repeated division and subsequent wall formation a mass of triploid tissue known as the endosperm, which surrounds the developing embryo. The endosperm nourishes the embryo during the early stages of its growth. In many plants such as the bean the endosperm is not formed at all or entirely absorbed by the developing embryo, while the seed is still immature; in others the endosperm forms a considerable part of the mature seed. Seeds with endosperm are known as albuminous seeds; those without endosperm as exalbuminous seeds.

The act of fertilization causes the immediate growth of the fertilized egg. In most plants, a series of cell divisions takes place, forming a short filament of cells which is called the proembryo. The appearance of the proembryo varies in different plants. The terminal cell of the proembryo becomes, by repeated cell divisions, a spherical mass of cells, which is the beginning of the true embryo. The embryo grows rapidly and becomes differentiated into three regions — a primitive root, or radicle, a primitive shoot, and cotyledons. This embryo is surrounded by the tissues of the nucellus and the integuments, which have grown larger to form seed coats coincident with the growth of the embryo. The mature ovule becomes the seed, and the ovary that contains it becomes the fruit.

FLOW MEASUREMENT (Liquids and Gases). There is a vital need to measure the rate of flow of liquids and gases as they move through pipes and conduits in many industrial manufacturing processes as well as in the operation of gas utilities and gas, oil, and water pipelines. Unlike solid materials, which can be measured *directly* by counting or weighing, fluids flowing through closed pipes or conduits normally require the measurement of some other variable that bears a mathematical relationship with rate of flow. Thus, in most instances, the flow of liquids and gases is by *inference* — that is, it is *indirect*. Flow measurement is required as the basis for automatically controlling processing operations and for cost and inventory control. One of the most common examples is the familiar bellows-type gas meter, upon which utility billings are based. Dispensing gasoline and other liquid fuels at the pump, and metering water consumption, also are excellent examples. Unlike these examples, where the flowing media are clean and noncorrosive, the chemical processing industries must measure corrosive and frequently toxic substances, for

which the flowmeters must be designed with engineered materials of construction.

The range of flow-measurement applications is extremely wide, varying from cryogenic temperatures up to as high as 3,000 °F (1,650 °C) and higher in some instances. Flowmeters are used to measure flows at pressures as low as 10^{-1} millimeters of mercury to as high as 15,000 psig (1,021 atmospheres). With advances in high-pressure technology, special flowmeters have been developed to operate at pressures in excess of 100,000 psig (6.804 atmospheres) and more. The nature of fluids measured varies from very clean, noncorrosive substances, such as pure water or air, to highly corrosive gases, such as chlorine. It also varies from liquids, such as sulfuric acid, to light, nonviscous gases of dense, highly viscous materials, some of which will only flow at elevated temperatures. Some fluids, such as slurries, contain high concentrations of suspended materials that will settle out rapidly unless kept in a turbulent condition.

A major factor contributing to wide diversity in flowmeter design is that of the magnitude of the flow to be measured — varying from perhaps a few cubic centimeters per hour, as encountered in medical and other laboratory research, to several millions of gallons per day, as found in large water and sewage systems.

It is not usual, therefore, to find that there are literally scores of flowmeter designs, each of which is well adapted to specific use conditions, but worthless for others. There is no universal flowmeter.

Classification of Flowmeters

From a practical standpoint, a convenient breakdown of flowmeter types (by operating principle) is as follows:

1. *Differential-producing flowmeters*, which operate by measuring the pressure differential or head across a suitable *restriction* to flow, such as an orifice placed in the pipeline.
2. Variable-area flowmeters, in which the restriction is a variable orifice. These meters also are called *rotameters*.
3. *Magnetic flowmeters*, the operating principle of which is based upon Faraday's law of electromagnetic induction.
4. *Turbine flowmeters*, in which a rotating device is positioned in the fluid path of a known cross-sectional area.
5. *Oscillatory flowmeters*, which sense a physical property of a moving fluid that infers fluid velocity.
6. Fluidic.
7. *Mass flowmeters*, which relate to either the Coriolis effect of a moving fluid mass or the thermal content of the flowing medium to indicate quantity of material flowing in terms of *mass*.
8. *Ultrasonic flowmeters*, which are based upon the interaction of ultrasound waves with the flowing medium. There are two types: the Doppler effect (frequency shift) design and the transit time design.
9. *Positive-displacement flowmeters*, which measure flow directly in quantitative terms by subdividing the flowing medium into discrete volumetric units. Principal designs include the nutating-disk meter, the oscillating-piston meter, the fluted rotor meter, and the oval-shaped gear meter.
10. *Open-channel flowmeters*, which translate a level measurement into terms of flow rate. Examples are the *weir* and the *flume*.

In the case of some flowmeters, the fluid being measured comes into intimate contact with the metering device per se and, in fact, several of the most commonly used methods require the presence of an object, such as an orifice, within the pipe. Where the pipeline must be broken in some fashion, the meter is sometimes called "intrusive" or wettable. In relatively few designs, as in the instances of some types of acoustic or ultrasonic flowmeters, flow is sensed from outside the pipe, and such meters may be called nonintrusive or nonwettable.

Differential-Producing Flowmeters

Also sometimes called head flowmeters, differential-producing meters remain among the most commonly used of all flowmeters — even though their technology has been basically the same for several decades. These meters today are at a very high state of engineering refinement and maturity. In this type of meter, the rate of flow, in quantity per unit time, is determined from the pressure drop or head across a restriction in the flow path. Common examples of this type of meter include orifice plates, venturi tubes, and flow nozzles. See also **Orifice**. This type of meter operates on the principle of energy conversion between static pressure and velocity. The velocity increase that results from a restriction in a line will have associated with it a decrease in static pressure. Thus, the flow rate may be determined from a measurement of the pressure drop or head, as it is commonly called. A sketch of a venturi meter together with a normal static pressure distribution, is shown in Fig. 1. A simple U-tube manometer is shown to indicate one method for measuring the head or pressure differential. Recording and controlling equipment may be actuated by directed measurements of the pressure differential. Although theoretical considerations will yield results within a few percent of actual flow rates, it is common practice to calibrate meters or to use experimentally determined correction factors. This is particularly true in the case of gas flow where the energy of the compressed fluid must be considered. References to detailed studies on this subject may be found in most standard works on hydraulics and fluid flow.

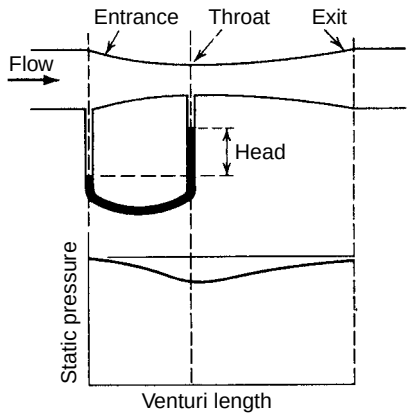

Fig. 1. Typical venturi meter and static pressure distribution.

Orifice plates available for installation in conduit range from $\frac{1}{2}$-inch to 72 inches (1.3 centimeter to 183 centimeters) and will normally have a range from 0 to 10 inches (25.4 centimeters) of water up to 1 to 400 inches (2.5 to 1016 centimeters) of water. In commercial meters, accuracy ranges from ±0.25 to 0.5% of fullscale. Advantages of orifice plates as the differential-pressure creators for flow measurement include: (1) low cost; (2) availability in numerous materials; (3) wide range of pipe sizes; (4) characteristics that are well known and predictable, with years of applicational experience; and (5) they can be used with simple types of differential-pressure devices. Some of the limitations of orifice plates include: (1) relatively high permanent pressure loss; (2) tendency to clog — not useful for slurries or entrained particles; (3) the flow rangeability for a given plate is limited to about 3:1; (4) square-root characteristics; (5) straightening vanes upstream often needed; (6) connecting piping problems encountered (freezing condensation, etc.) unless orifice is integral with a transmitter; (7) characteristics tend to change with time of use due to erosion, corrosion, and sealing; and (8) accuracy is dependent upon care during installation.

A *flow nozzle*, often used instead of an orifice plate, consists of a bell-shaped approach section of eliptical profile attached to a cylindrical throat tangent to the ellipse. The smoothness of the approach to tangency, the length of the cylindrical portion of the nozzle, and the locations of the pressure taps have an important bearing on the discharge coefficient. Flow nozzles are normally available in pipe sizes from 3 to 24 inches (7.6 to 61 centimeters) (diameter). Advantages claimed for flow nozzles include: (1) under proper installation conditions, permanent pressure loss can be a bit lower than the orifice plate; (2) available in numerous materials; (3) can be used with simple types of differential-pressure devices; (4) can handle fluids containing solids that settle; and (5) widely acceptance performance for high-pressure/temperature steam flow. Limitations include: (1) higher cost than orifice plate; and (2) limited to moderate pipe sizes, with a top of about 48-inch (122-centimeter) diameter in special cases. See Fig. 2.

The *venturi tube*, as shown in Fig. 1, creates a much smaller permanent pressure loss than the orifice plate and hence is attractive for numerous installations. Other advantages include: (1) handles suspended solids; (2) available in very large pipe sizes — widely used for large flows, as in water and sewage plants; (3) available in numerous materials of construction; (4) characteristics well established with years of applicational

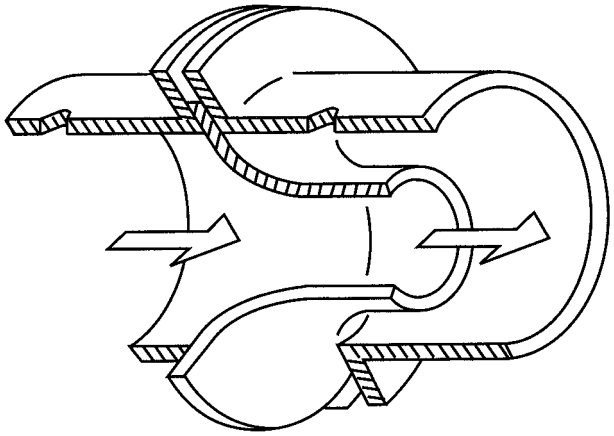

Fig. 2. Flow nozzle designed to reduce pressure loss of fluid flowing through a traditional orifice plate.

experience; and (5) best accuracy for head flowmeter differential producers. Its limitations include high cost and unavailability generally for pipe diameters below 6 inches (15 centimeters).

The *pitot tube*, described in entry on **Pitot Tube**, also is used for making flow measurements in closed conduits, with a general range of pipe diameters from 3 to 48 inches. However, the device is of relatively minor importance in commercial flow measurement. It is an effective tool for laboratory use or for spot checks, but its tendency to plug when the flowing fluid contains small amounts of solid matter, its velocity-range limitations, and its sensitivity to abnormal velocity-distribution effects limit its commercial usefulness. See Fig. 3.

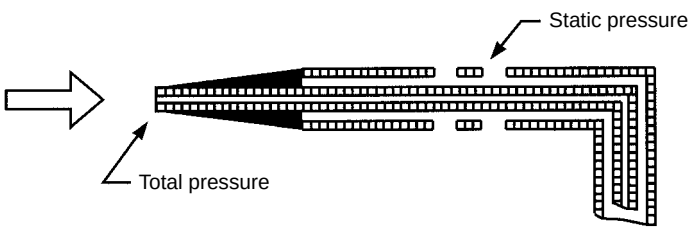

Fig. 3. Pitot tube.

In recent years, a number of additional differential-producing type flowmeters have been designed. Three of these are shown in Figures 4, 5, and 6. The target flowmeter, shown in Fig. 7, is also a form of differential-producing flowmeter.

Variable-Area Flowmeters. As in head flowmeters just described, differential pressure is the measure of flow rate. In the orifice meter, there is a fixed aperture to create the differential pressure. In the variable-area design, a variable orifice is used, with a relatively constant pressure drop. Thus, flow rate is indicated by the area of the annular opening through which the flow must past. This area generally is read out as the position of a float or obstruction in the orifice.

Frequently referred to as a *glass tube flowmeter* or *rotameter*, these meters are designed in three configurations. (1) *Tapered tube meter*, in which a float (usually of a density greater than the fluid being measured) is contained in an upright glass tube, which is tapered. That is, the bottom of the tube is of a somewhat smaller diameter than at the top. Thus, the area or concentric orifice through which the fluid flows is greater as the float rises in the tube. (2) The term *rotameter* was coined many years ago from the early technology wherein the rotor was slotted and thus rotated by the flowing fluid. The float no longer is designed to rotate, but it is lifted to a position of equilibrium between the downward (gravity) force and that of the upward force caused by the flowing medium.

(3) The *orifice and tapered plug meter*, which is equipped with a fixed orifice mounted in an upright chamber, is another version of this class of meters. The float has a tapered body, with the small end at the bottom, and it is allowed to move vertically through the orifice. The fluid flow causes the float to seek an equilibrium position.

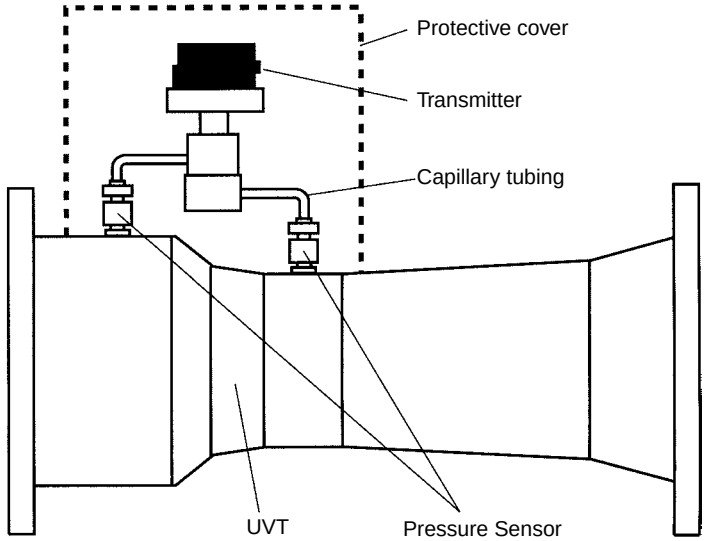

Fig. 4. A universal venturi primary (UVT), equipped with an electronic flow transmitter. Differential pressure is statically sensed by units that are mounted flush with the inside of the venturi tube. Units like this are used in connection with solids-bearing fluids, such as waste water or light slurries. The system is designed to eliminate clogging or contaminant buildup. A 4–20 mA dc signal is produced. System accuracy is ±1.0% over a 10:1 range. (*Leeds & Northrup: BIF Products.*)

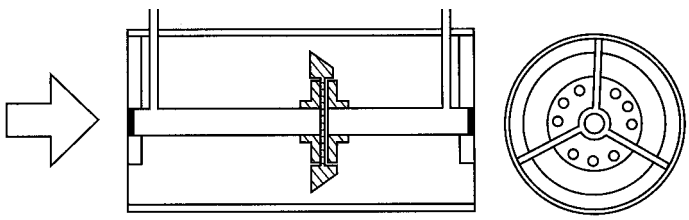

Fig. 5. Annular orifice. This design was developed to overcome the problem of dirt buildup in front of an orifice in a liquid stream and of liquid buildup in a moist gas stream. Total (stagnation) pressure taps and rearward-facing taps produce a high differential for a given beta ratio, redefined here as the ratio of disk diameter to pipe diameter.

In still another format, the *piston-type meter* utilizes a piston that is accurately fitted inside a sleeve and is uncovered to permit the passage of fluid. Flow rate is indicated by position of the piston.

Schematic diagrams of these various designs are given in Fig. 8.

Magnetic Flowmeters (Magmeters). The magnetic flowmeter has numerous advantages for measuring liquids that are electrically conductive. This is also a factor, which limits its use in terms of nonconducting fluids. Where applicable, the magmeter is quite advantageous in terms of difficult fluid measuring problems, including corrosives, viscose, sewage, rock-and-acid slurries, paper pulp stock, rosin size, detergents, tomato pulp, beer, and other fluids encountered in the chemical and food processing fields. The magmet can be adapted as a controller for batching, as may be found in brewery and bottling plant batching operations, where it operates with an accuracy of ±.2%.

Early magmeter designs were full-line devices that were quite costly, heavy, and bulky. In more recent years, some *insertion* configurations have been developed. In such designs, the sensor can be introduced through a hole in a large pipeline or by a T-fitting in a small line. Although the same accuracy generally is not achieved with in-line models, these designs do offer lower initial cost, ease of installation, and lower maintenance. As of the early 1990s, some authorities consider that the Coriolis mass flowmeter will become a serious rival for traditional magmeter applications.

With reference to Fig. 9, the magmeter comprises: a tube through which the measured fluid passes, coils, a laminated iron core, a cover, and end connections. Traditionally, the tube has been constructed of nonmagnetic stainless steel or fiberglass laminated plastic. Research on nonconducting materials to prevent the generation of emf from short-circuiting continues. Contemporary ceramic liners approach the desired characteristics (i.e.,

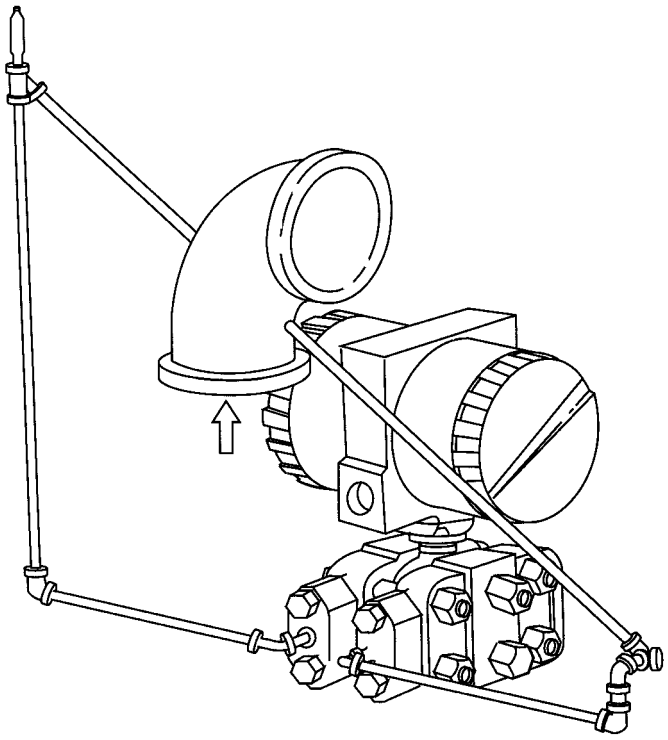

Fig. 6. Highly schematic representation of an elbow flowmeter. As a fluid passes through a pipe elbow, the pressure increases at the outside radius of the elbow because of centrifugal force. If pressure taps are located at the outside and inside of the elbow (either at 25° or 45°), a reproducible measurement can be made. Taps located at angles greater than 45° are not recommended because flow separation may cause erratic readings. Many flow piping systems have elbows. The system is relatively low cost. Elbows are not always consistently constructed and thus limit the accuracy, but precision (repeatability) is considered good. Some models offer proprietary machined elbows for improved accuracy. Very low differential is produced, particularly for gas flows.

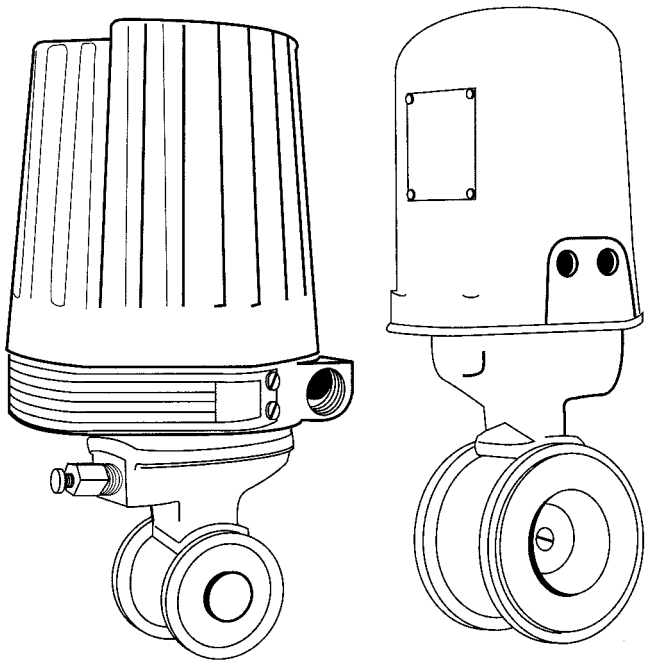

Fig. 7. Target flowmeter (*Foxboro*.) This flowmeter has the features of an annular orifice, but without the disadvantages of freezing or plugging lead lines. The primary element consists of a sharp leading edge disk (target) fastened to a bar. Differential pressure produced by the reduced annular area creates a disk drag force. This force is transmitted through the bar to an appropriate force-measuring secondary device. The flow rate is calculated as the square root of this output. Target flowmeters are well suited for liquids, gases, vapors, dirty fluids, light slurries, and high-viscosity liquids.

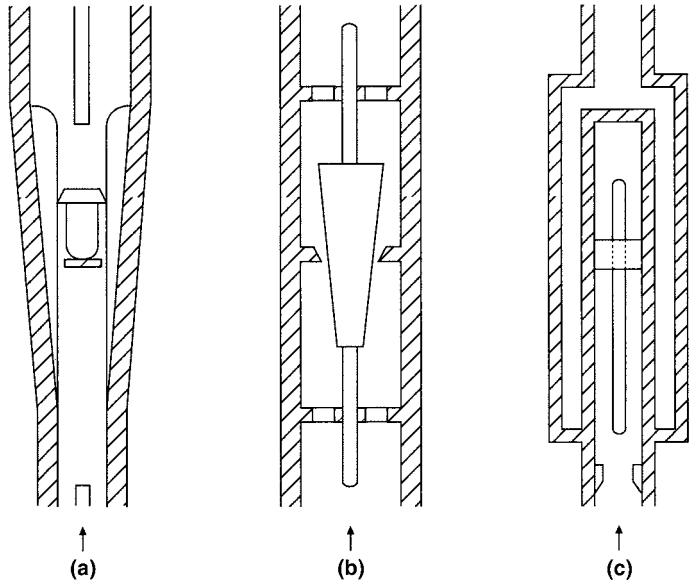

Fig. 8. Schematic views of the three basic types of variable-area flowmeters: (**a**) tapered tube (rotameter), (**b**) orifice and tapered plug, (**c**) cylinder and piston.

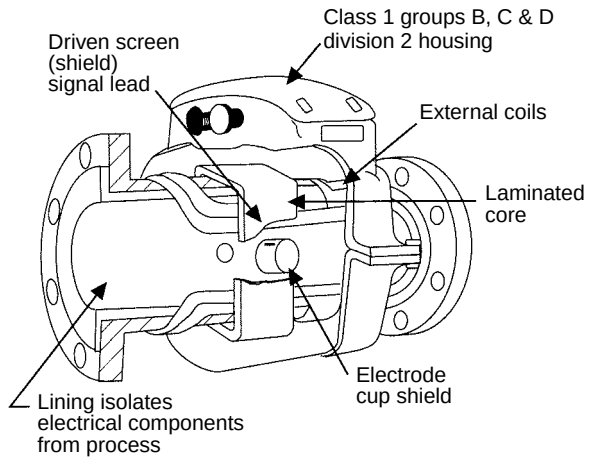

Fig. 9. Layout of essential components of a magnetic flowmeter.

in satisfying the electrical requirements as well as in coping with the corrosiveness and other characteristics of the measured fluid).

Operation of the magmeter is based upon Faraday's law of electromagnetic induction, which states that the voltage E induced in a conductor of length d moving through a magnetic field h is proportional to the velocity v of the conductor. Thus,

$$E = Chdv$$

where C is a dimensional constant. See Fig. 10.

A schematic cross section of a magmeter is shown in Fig. 11. Generally, a magmeter generates a voltage that is proportional to the *average* fluid velocity of the profile at the plane of the electrodes. This results from the fact that each element of fluid in the electrode plane develops an element of voltage that is in proportion to its instantaneous velocity. The voltage sensed at the electrodes is proportional to the sum of these elements of generated voltage and, therefore, accurately represents the average velocity of the fluid in the plane. This voltage represents the *volumetric* flow, provided that the tube is completely filled with fluid at all times. Designs with four electrodes have been introduced in order to cope more effectively with the velocity profile problem.

Direct current magmeters are somewhat smaller, have a more stable zero, and are lower in cost as compared with the earlier AC designs. However, in handling slurries with small particles, a low-frequency noise on the flow signal can result — this is caused by particles scraping the electrodes as they flow by. There is considerable research underway, to develop special circuits that may minimize this noise problem.

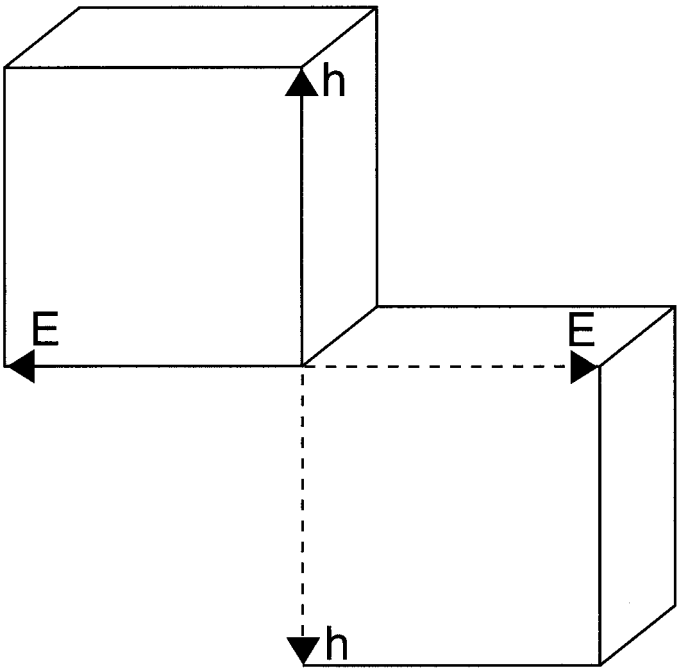

Fig. 10. Graphic representation of formula applying to magnetic flowmeter.

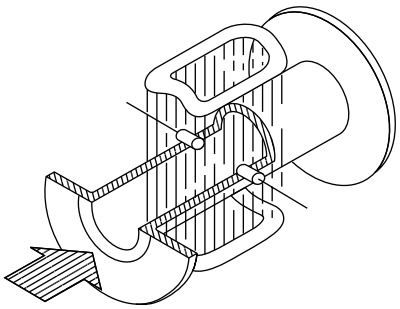

Fig. 11. Essential elements of a practical magnetic flowmeter. (*Foxboro*.)

Dual-frequency excitation also has been introduced into magmeter circuitry. As shown by Fig. 12, the magnetic field coils are excited by current with a compound waveform.

Microprocessors and other sophisticated electronics can provide multirange, low liquid flow cut-off, bidirectional flow measurement, self-diagnostics, and loop tests, among other requisites for system integration.

Turbine Flowmeters. Turbine flowmeters consist of a rotating device, called a *rotor*, positioned in the fluid path of a known cross-sectional area, the body or pipe. This is done in such a manner that the rotational velocity of the rotor is *proportional* to the *fluid velocity*. Since the cross-sectional area of the pipe is known, fluid velocity can be converted directly into volumetric flow rate by counting the number of turbine wheel revolutions per unit of time. See Fig. 13.

Turbine flowmeters accurately measure flow over a large range of operating conditions. Primary uses include flow totalizing for inventory control and custody transfer, precision automatic batching for dispensing and batch mixing, and automatic flow control for lubrication and cooling applications. Typical measurement accuracy is ±0.5% of reading over a 10:1 flow range (turn-down ratio) and repeatability within ±0.0% of rate. A degradation in performance can be expected if there are variations in fluid viscosity, swirling of fluid within the pipe, or contamination that causes premature bearing wear. Turbine flowmeters are available for pipe sizes from $\frac{1}{2}$ in (12.7 mm) to 24 in (610 mm), and flow ranges to 50,000 gpm (11.358 m^3/h). Standard meters operate up to a temperature of 400 °F (204 °C) and can be specially ordered for temperatures up to 800 °F (427 °C).

Paddle-wheel flowmeters are closely related to turbine flowmeters and take the form illustrated in Fig. 14. The paddle-wheel flowmeter requires a full pipe for operation. These meters cost less than turbine meters and

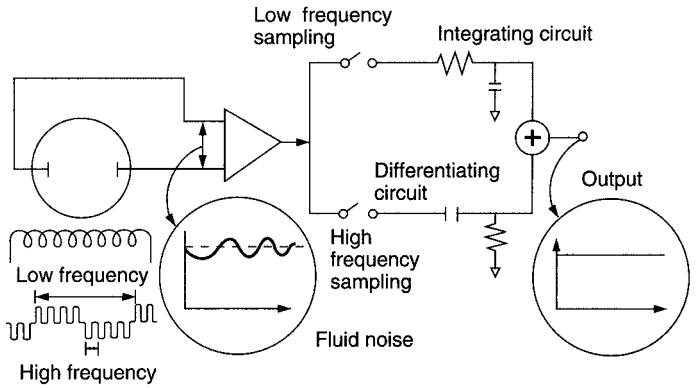

Fig. 12. Dual-frequency excitation method. The magnetic field coils are excited by current with a compound waveform. One component has a rectangular waveform with a frequency greater than line frequency (60 Hz). This provides a signal that is immune to the low-frequency noises generated by electrochemical reactions, high viscosities, and/or in low-conductivity liquids. The second component is a rectangular waveform with a frequency much less than line frequency. This provides a large improvement in zero stability.

The low-frequency component is integrated via a long time constant to provide a smoother, more stabilized flow signal. The high-frequency component is conditioned by high-frequency sampling and processed in a differentiating circuit with the same time constant as the integrating circuit. By adding these two signals, a flow signal is obtained that is free from "slurry noise," in addition to other advantages. (*Yokogawa*.)

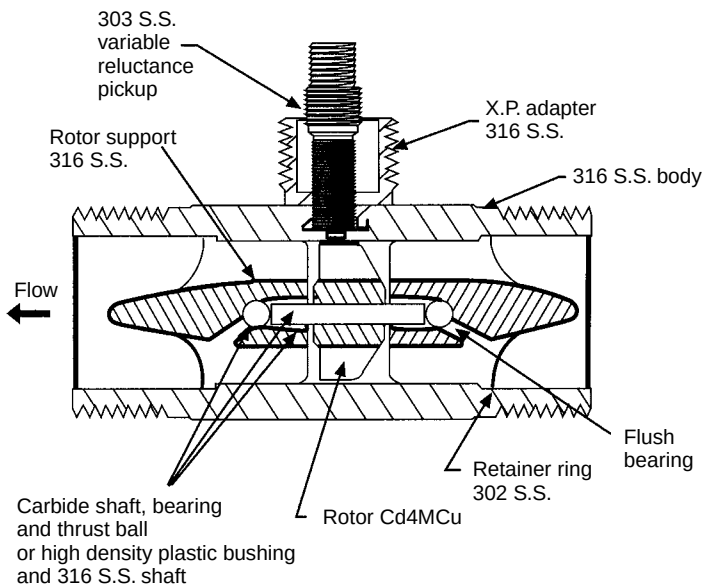

Fig. 13. Typical axial rotor [$\frac{1}{2}$ in (12.7 mm) to 3 in (76.2 mm)] turbine flowmeter construction. (*Great Lakes Instruments, Inc*.)

have somewhat less accuracy and reproducibility than their turbine meter counterparts.

Oscillatory Flowmeters. As with the turbine flowmeters just described, the oscillatory meters sense a physical property of a moving fluid that is related to *stream velocity*. There are two principal types of meters: (1) *vortex meters* and (2) *fluidic meters*.

Vortex flowmeters utilize the principle of vortex shedding, a phenomenon that has been known for several years, but that has found practical application only since the mid-1970s. Vortex meters now are widely used, the installations numbering in the tens of thousands. The vortex meters have made a major impact on the use of orifice-type meters.

Vortex formation can occur when a nonstreamlined obstruction is placed in a flowing stream. The obstruction, sometimes referred to as the *shedder*, must be designed and shaped to produce vortices that create a differential pressure of sufficient magnitude to be detected. Considerable research has gone into the design of shedding elements. See Fig. 15. In another

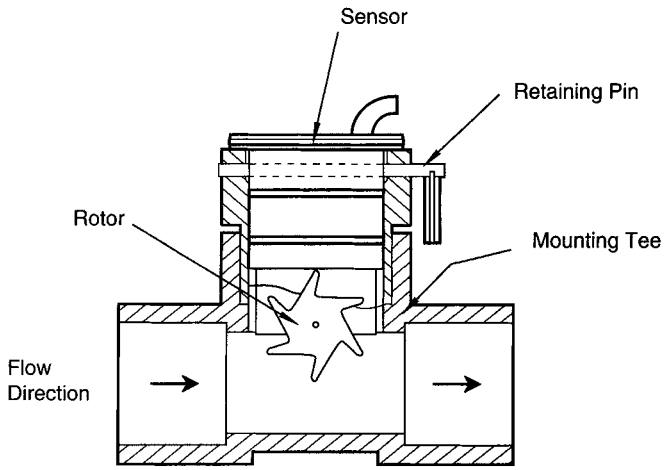

Fig. 14. Typical paddlewheel flowmeter construction. (*Great Lakes Instruments, Inc.*)

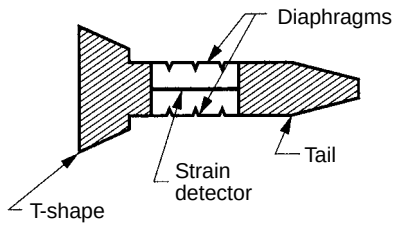

Fig. 15. Cross section of a shedding element. The face of the T-shape end is sometimes referred to as a *bluff body*. The tail is very important in the control of stable vortex shedding and also provides a good location for the vortex detector because the signal-to-noise ratio at this location is high. The location also provides good protection for the detector from any objects that may be in the fluid stream. (*Foxboro.*)

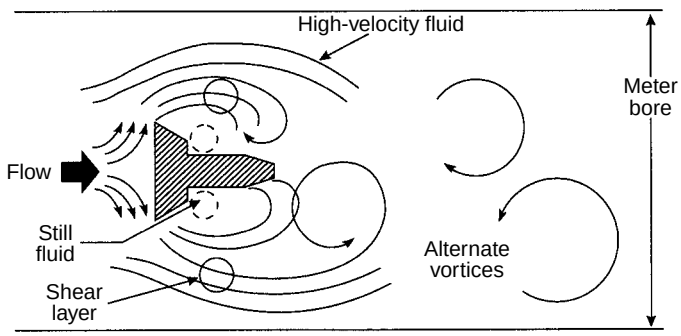

Fig. 16. Vortex shedding phenomenon. Flow patterns are altered by presence of obstruction (a shedding element.)

vortex meter design, the rate of processing vortices or whirlpools is sensed.

As shown in Fig. 16, as the fluid flows through the flowmeter, it is divided into two paths by the shedding element, which is positioned across the flowmeter body. High-velocity fluid parcels flow past the lower-velocity parcels near the element to form a sheer layer. There is a large velocity gradient within this sheer layer, thus making it inherently unstable. After some length of travel, the sheer layer breaks down into well-defined vortices. Differential-pressure changes occur as the vortices are formed and shed. This pressure variation is used to actuate a sealed detector at a frequency proportional to vortex shedding.

With further reference to Fig. 15, the detector may consist of a double-faced circular diaphragm capsule filled with a liquid. A piezoelectric crystal may be located in the center of the capsule in such manner that the vortex-produced pressure changes are transmitted through the fill liquid to the crystal, whereupon the piezoelectric crystal produces a voltage output when a pressure change is detected. The alternate vortex generation reverses the differential, and a voltage of opposite polarity is generated. Thus, a train of vortices generates an alternating voltage output with a frequency identical to the frequency of vortex shedding.

Fluidic Flowmeters. Fluidics is the technology of sensing, controlling, and information processing, with devices that use a fluid medium and the operation of which is based solely on the interaction between fluid streams. The particular function of each device, none of which has any moving parts, is dependent on the geometric shape of the device. Fluidics received considerable attention from the military in the 1960s as a control medium that could not be jammed, as is possible with unprotected electronic devices. The wall attachment fluid phenomenon (also called the Coanda effect) was first discovered by Henri Coanda, a Rumanian engineer in 1926. The possible industrial application of fluidics was explored in the 1960s, with the creation of amplifiers, valves, oscillators, flowmeters, and other configurations.

Industrial fluidic flowmeters are currently available. These incorporate the principle of the fluidic oscillator shown in Fig. 17. In flowmeter applications, the fluidic oscillator has the advantages of:

1. Linear output with the frequency proportional to flow rate;
2. Rangeability up to 30:1;
3. Unaffected by shock, vibration, or field ambient temperature changes;
4. Calibration in terms of volume flow unaffected by fluid density changes; and
5. No moving points and no impulse lines.

See Fig. 18.

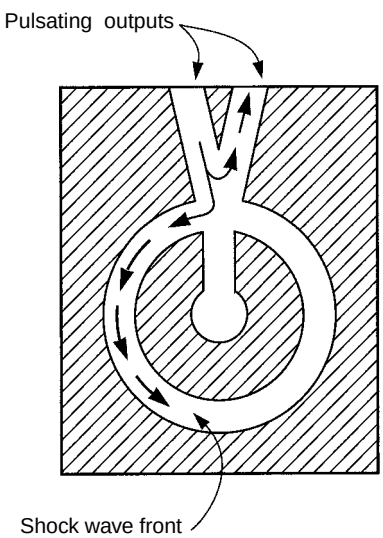

Fig. 17. Fluidic oscillator.

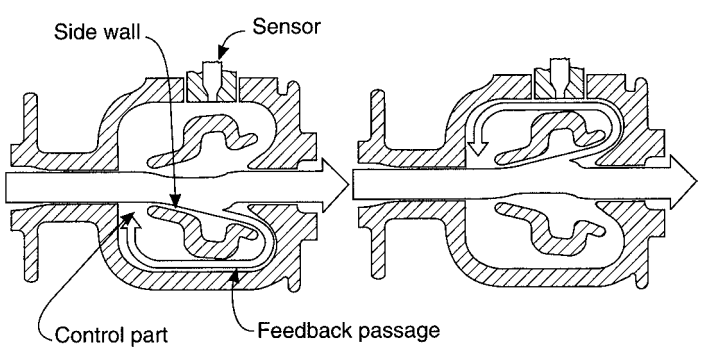

Fig. 18. Operating principle of a fluidic flowmeter. The geometric shape of the meter body is such that, when flow is initiated, the flowing stream attaches to one of the side walls as a result of the Coanda effect. A portion of the main flow is diverted through a feedback passage to a control port. The feedback flow increases the size of the separation bubble. This peels the main flow stream away from the wall until it diverts and locks onto the opposite wall, where the feedback action is similar. The frequency of the self-induced oscillation is a function of the feedback flow rate, which in turn is directly proportional to the flow rate of the mainstream. (*Moore Products.*)

A similar fluidic flowmeter, but without diverging sidewalls, uses momentum exchange instead of the Coanda effect and has also proved effective in metering viscous fluids.

See also **Fluids**.

Mass Flowmeters. Traditionally, fluid flow measurement has been made in terms of the *volume* of the moving fluid, even though the meter user may be more interested in weight (mass) of the fluid. Volumetric flowmeters also are subject to ambient and process changes, such as density, which changes with temperature and pressure. Viscosity changes also may affect volumetric flow sensors.

Thus, for a number of years, there has been much interest in finding ways to measure mass directly, rather than to employ calculating means to convert volume to mass. As of the early 1990s, there are three ways to determine mass flow:

1. The application of microprocessor technology to conventional volumetric meters;
2. The use of Coriolis flowmeters, which measure mass flow directly; and
3. The use of thermal mass flowmeters, which infer mass flow by way of measuring heat dissipation between two points in the pipeline.

The latter two concepts have been investigated and attempted for several years, but were not practical nor commercially available in fairly large numbers until the mid-1980s.

Coriolis Flowmeters. Although the Coriolis effect was considered many years ago, serious work in terms of applying the principle to instrumentation and, in particular, to flowmeters did not occur until the mid-1970s. A formal introduction into the marketplace occurred in the early 1980s. Since then, numerous design improvements have been made, including a reduction of side effects brought about by ambient vibrations. As of the early 1990s, these meters were installed in several thousand applications throughout the world. See separate encyclopedia entry on **Coriolis Effect**.

The complete Coriolis unit consists of (1) a Coriolis force sensor and (2) an electronic transmitter. The sensor comprises a tube (or tubes) assembly that is installed in the process pipeline. As shown by Fig. 19, in one configuration, a U-shaped sensor tube is vibrated at its natural frequency. The angular velocity of the vibrating tube, in combination with the mass velocity of the flowing fluid, causes the tube to twist. The amount of twist is measured with magnetic position detectors, producing a signal that is linearly proportional to the mass flow rate of every parcel and particle passing through the sensor tube. The output is essentially unaffected by variations in fluid properties, such as viscosity, pressure, temperature, pulsations, entrained gases, and suspended solids.

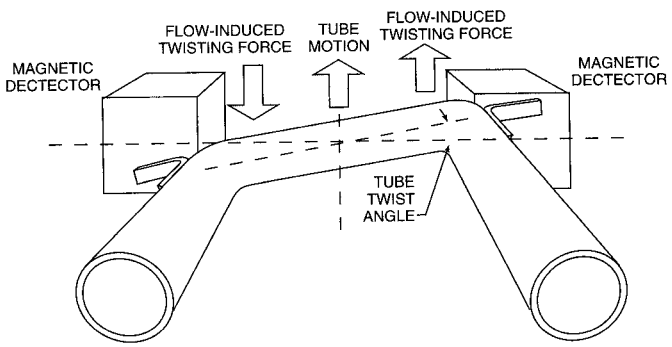

Fig. 19. Operating principle of Coriolis mass flowmeter. (*Micro Motion.*)

There is no contact with the flowing fluid except with the inside wall of the tube, which usually is made of stainless steel or some other corrosion- and erosion-resistant material. Two magnetic position detectors, one on each side of the U-shaped tube, generate signals that are routed to the associated electronics for processing into an output.

Thermal Mass Flowmeters. Like the Coriolois meter, after many years of design work and limited applications, the thermal mass flowmeter did not become widely accepted until the late 1970s.

A thermodynamic operating principle is used. As shown in Fig. 20, a precision power supply directs heat to the midpoint of a sensor tube that

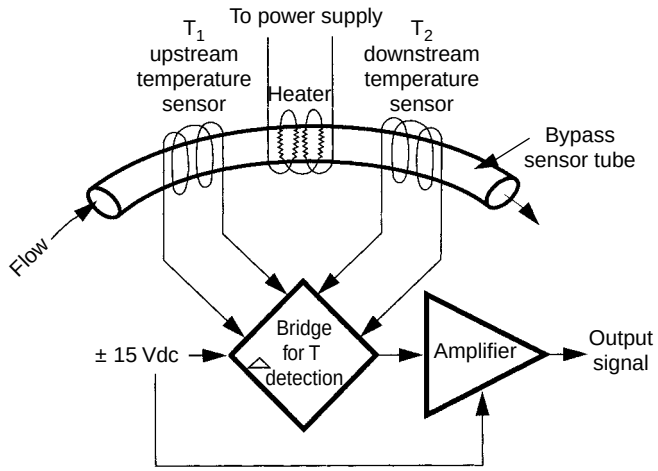

Fig. 20. Operating principle of the thermal mass flowmeter. (*Brooks.*)

carries a constant percentage of the flow. On the same tube, equidistant upstream and downstream of the heat input, are resistance temperature detectors (RTDs). With no flow, the heat reaching each temperature element is equal. With increasing flow, the flow stream carries heat away from the upstream element (T1) and an increasing amount toward the downstream element (T2). An increasing temperature develops between the two elements, and this difference is proportional to the amount of gas flowing, or the *mass flow rate*. A bridge circuit interprets the temperature difference, and an amplifier provides the 0–5 VDC and 4–20 mA output signal.

Ultrasonic Flowmeters. Ultrasonic flowmeters are of two principal types: (1) *Doppler-effect* (frequency-shift) and (2) *transit-time* flowmeters. See also **Doppler Effect**.

Doppler-effect flowmeters utilize a transmitter that projects a continuous ultrasonic beam at about 0.5 MHz through the pipewall into the flowing stream. Particles in the stream reflect the ultrasonic radiation, which is detected by a receiver. The frequency of the radiation reaching the receiver is shifted in proportion to the stream velocity. The frequency difference is a measure of the flow rate. The configuration of Fig. 21(**a**) utilizes separate dual transducers mounted on opposite sides of the pipe. Other possible configurations are shown in Fig. 21(b). In essence, the Doppler-effect meter measures the beat frequency of two signals. The beat frequency is the difference frequency obtained when two different frequencies (transmitted and reflected) are combined.

Transit-time ultrasonic flowmeters must be reasonable conductors of sonic energy. At a given temperature and pressure, ultrasonic energy will travel at a specific velocity through a liquid. Since the fluid is flowing at a certain velocity, the sound will travel faster in the direction of flow and slower against the direction of flow. By measuring the difference in arrival time of pulses traveling in a downstream direction and of pulses traveling in an upstream direction serves as a measure of fluid velocity. Transit-time flowmeters transmit alternately upstream and downstream and calculate the time difference. See Fig. 22.

Positive-Displacement Flowmeters

Positive-displacement meters, in contrast to variable-head and area meters, are used to measure total flow rather than flow rate. In this type of meter, a fixed quantity of fluid will produce a given motion or rotation to a piston or vane, which through some registering device will then indicate or record the quantity. Since there is a positive displacement of the meter for each quantity of fluid, the time factor is not involved.

Nutating-Disk Meter. The household water meter is probably the most common example of this type of meter. The accuracy of this type of meter over a wide range of flow rates makes it ideally suited to applications involving varying flow rates over long periods of time. A nutating-disk meter is shown in cross section in Fig. 23. Although there are design differences from one manufacturer to the next, the basic operation of the meter is as shown in Fig. 24. Each cycle (complete movement) of the measuring disk displaces a fixed volume of liquid. The only moving part in the measuring chamber is the disk. The liquid enters through the inlet

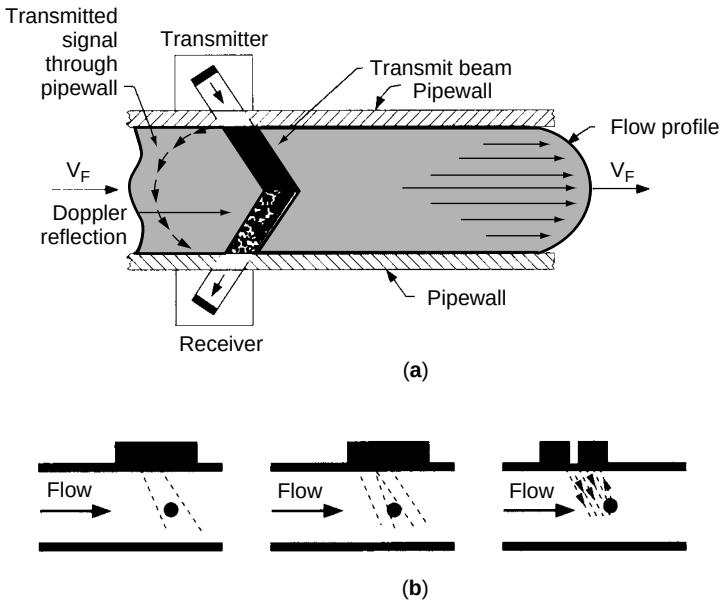

Fig. 21. Variations of Doppler-effect flowmeters. (**a**) Separate (opposite side dual) transducers are used. (**b**) A single transducer is used at left, a tandem dual transducer is shown in the middle, and separate dual transducers are installed on same side of pipe as shown at right.

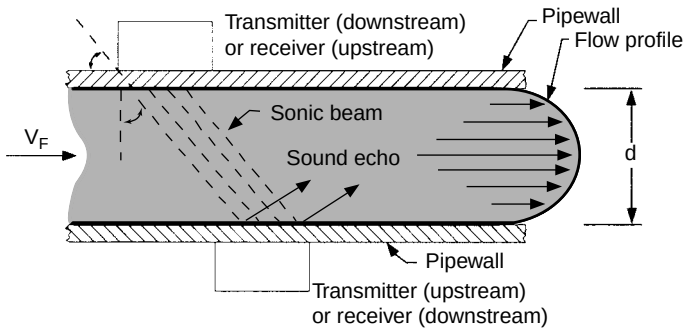

Fig. 22. Principle of transit-time ultrasonic flowmeter known as the "clamp-on" type. Transducers alternately transmit and receive bursts of ultrasonic energy.

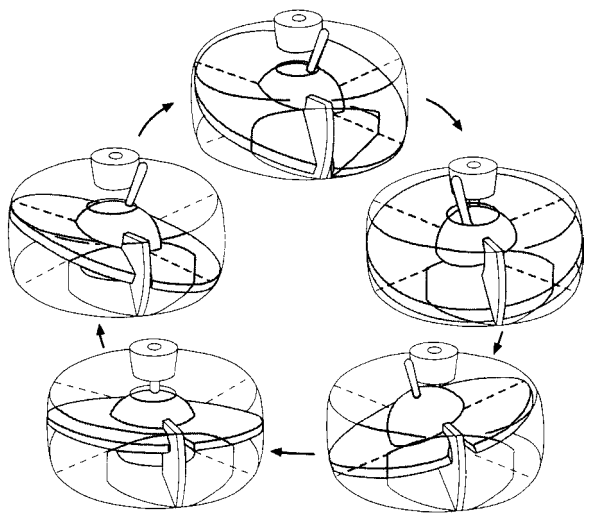

Fig. 24. Principle of operation of nutating-disk meter.

port and fills the spaces above and below the disk, which fits closely and precisely in the measuring chamber. As liquid moves into the chamber, the disk is moved in a nutating path. The motion of the disk is controlled by a cam that keeps the lower face in contact with the bottom of the measuring chamber on one side. Mean while, the upper face of the disk is in contact with the top of the chamber on the opposite side. Meters of this type are generally available for pipe diameters from $\frac{1}{2}$ inch to 2 inches (1.3 centimeters to 5.1 centimeters) with a flow rate ranging from two gallons (7.6 liters) per minute minimum up to about 160 gallons (606 liters) per minute.

Oscillating-Piston Meter. The operating principle of the oscillating-piston meter is similar to that of the nutating-disk meter. The important contrast is that the mechanical motion takes place in one plane (no wobble). Pipe sizes range from $\frac{1}{2}$ inch up to 2 inches (1.3 centimeters to 5.1 centimeters). Flow rates range from 0.75 up to 160 gallons (2.8 liters to 606 liters) per minute. The meter has good accuracy, especially for low flow rates. It is easy to install, maintain, and is readily adaptable to automatic liquid-batching systems. It possesses limited power in terms of driving mechanical accessories.

Rotating Meters. The principal positive-displacement meters of the rotating type are the lobed-impeller flowmeter and the sliding-vane and retracting-vane rotary meters. In the *lobed-impeller meter* (Fig. 25) two rotors revolve with fixed relative position inside a cylindrical housing. The measuring chamber is formed by the wall of the cylinder and the surface of one-half of one rotor. When the rotor is in a vertical position, a definite volume of fluid is contained in the measuring compartment. As the impeller turns, owing to the slight pressure differential between

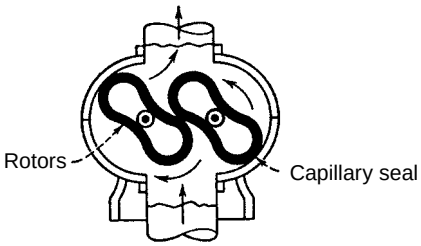

Fig. 25. Lobed-impeller flowmeter.

inlet and outlet ports, the measured volume is discharged through the bottom of the meter. This action occurs four times for a full revolution, the impeller rotating in opposite directions and at a speed proportional to the volume of fluid flow. These meters are available in pipe sizes from $1\frac{1}{2}$ to 24 inches (3.8 to 61 centimeters) (diameter) for handling from 8 gallons (30 liters) per minute up to 25,000 barrels (39,743 hectoliters) per hour, with an accuracy of about ±0.20%. Advantages include performance at relatively high temperatures (400 °F; ~205 °C) and pressures up to 1,200 psi (81.6 atmospheres). The meters have a low pressure loss, are available in numerous materials of construction, applicable to gases and a wide range of light to viscous liquids, including asphalt. Limitations include susceptibility to damage from entrained vapors, tendency to be bulky and heavy in larger sizes, relatively high cost, and slip at low flow rates (they are best used at high rates).

As illustrated in Fig. 26, in the *sliding-vane rotary flowmeter*, vanes are moved radially as can followers to form the measuring chamber. In the *retracting-vane version* of Fig. 27, the vanes are articulated. The sliding-vane type contains a cylindrical rotor that revolves on ball bearings around a central shaft and stationary cam. As fluid flows against an extended blade, the resulting rotation of the rotor and action of the cam cause the blades to act as cam followers, creating measuring chambers that measure fluid throughput. Capillary action of the metered fluid seals the blades to form measuring cavities. In the retracting vane design, fluid entering the meter is deflected downward against the extended blade, causing rotation of the measuring element. Sealing of the metering chamber is accomplished by incorporating features of the piston-ring seal. The vanes or blades, coated with a resilient material, are spring-loaded to provide the wiping action of a piston ring. Both of the vane-type rotary meters are useful up to temperature of 400 °F (±205 °C) and pressures up to 500 psi (34 atmospheres) (sliding-vane type) and 900 psi (61 atmospheres) (retracting-vane type). Sliding-vane meters are available in pipe sizes up to 16 inches (41 centimeters); retracting-vene meters are limited to maximum size of 4-inch (10-centimeter) pipes.

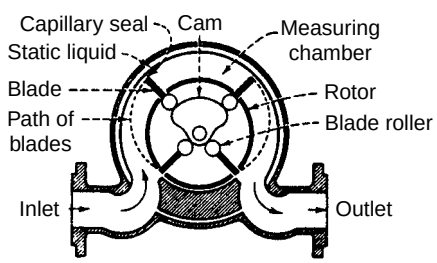

Fig. 26. Sliding-vane rotary meter.

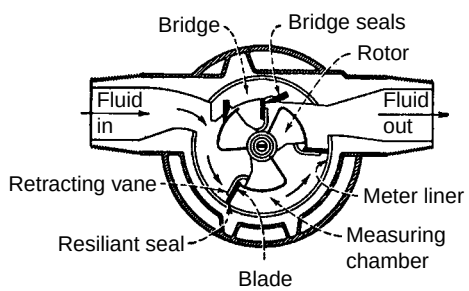

Fig. 27. Retracting-vane rotary meter.

Bellows Gas Meter. The type of meter is widely used in both commercial and domestic gas service. It is comprised of four measuring compartments, which operate simultaneously. Some of the compartments are filling while others are emptying, but all are always conforming to set conditions, thereby insuring a uniform delivery of gas. The number of times each measuring chamber is filled and emptied is registered, thus indicating the total volume in cubic feet on the index. The register or meter is operated from a crank that is rotated by movement of the diaphragms. Synthetic rubber diaphragms are usually used to insure that displacement is directly proportional to stroke. Two valves of the D-slide type are actuated by a central crank via a suitable linkage. Motion of the meter mechanism cannot occur unless a pressure differential (hence gas flow) takes place. Normally, a pressure differential of 0.10-inch (2.5 millimeters) of water will commence actuation of the meter. Maximum capacities range from 150 to 17,000 cubic feet (4.2 to 481 cubic meters) per hour.

Open-Channel Flowmeters. The flow-measurement principles previously described generally are not applicable to the measurement of large-volume flows encountered in open channels, as encountered, for example, in the measurement of water and sewage. Irrigation water measurement is a very important example. For these types of applications, weirs and flumes are the principal measurement means used. In certain applications, the Kennison nozzle is also used.

Weirs. A weir consists of a partition or bulkhead of timber, concrete, sheet metal, or other fabrication, having in its top edge an opening of fixed dimensions through which a stream can flow. The opening is called the weir notch, and its bottom edge is the crest. The depth of water passing over the crest is the head (must be measured at a definite point upstream from the weir); the sheet of water flowing through the notch and over the weir crest is called the nappe. When the weir has a sharp upstream edge so that the nappe springs clear of the crest, it is called a sharp crested weir. The nappe, immediately after leaving a sharp crested weir, suffers a contraction along the horizontal crest called crest contraction. If the sides of the notch have sharp upstream edges, the nappe also is contracted in width, and the weir is said to have end contractions. With sufficient side and bottom clearance dimensions of the notch, the nappe suffers maximum crest and end contractions, and the weir is said to be fully contracted. Of the various types of weirs, the three most commonly used are described briefly as follows:

V-Notch Weir — This device is particularly recommended for metering flows less than one cubic foot (0.03 cubic meter) per second (equivalent to 0.65 million gallons (24,603 hectoliters) per day) and is suitable for measuring slowly changing flows up to 10 cubic feet per second. Extensive experiments have been made to determine the calibration data for V-notch weirs with included angles of 60° and 90°; two acceptable formulas are given in Fig. 28.

Rectangular Weir — This device is capable of high-capacity metering and is simple and inexpensive to construct. To assure complete contraction of the nappe, the side and bottom clearance dimensions of the notch must equal or exceed those shown in Fig. 28. The traditional formula for discharge of water through a suppressed rectangular weir is the Francis formula as indicated in Fig. 28.

Cipolletti Weir — This weir, also shown in Fig. 28, is similar to the rectangular weir except for sloping sides (1 horizontal to 4 vertical) of the notch. The design has the advantage of a simplified discharge formula that is more convenient to handle.

Other weirs include the hyperbolic (Sutro), broad crested, and round crested weirs.

Parshall Flumes. The Parshall venturi-type flume consists of a converging upstream section; a downward sloping throat; and an upward sloping, diverging downstream section. It is usually made of reinforced concrete, but may be of wood and, because of size, usually constructed on the site. Stainless steel and fiber glass reinforced plastic liners have been used for metering corrosive solutions. Surfaces are true planes, finished smooth with close adherence to specified dimensions. Parshall flumes have been constructed in sizes with throat widths ranging from 3 inches (7.5 centimeters) to 40 feet (12 meters) for measuring flows up to many million gallons per day. Some idea of the general shape of a Parshall flume can be gleaned from Fig. 29.

Kennison Nozzle. This device is an unusually simple device for measuring flows through partially filled pipes. The nozzle successfully copes with low flows, wide flow ranges, and liquids containing suspended

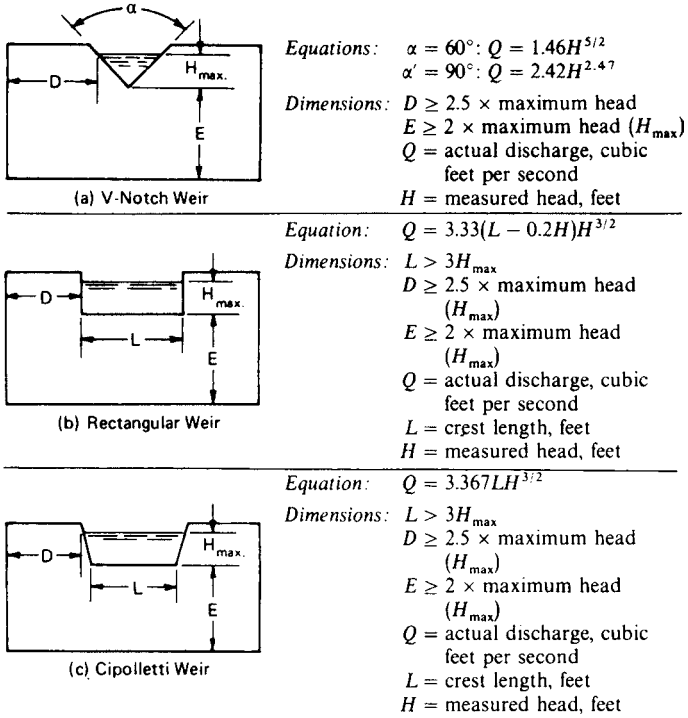

Fig. 28. Principal types of weirs.

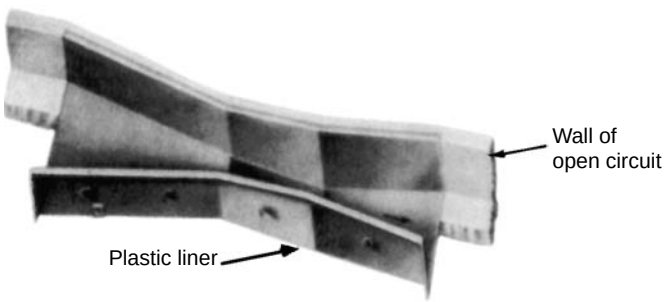

Fig. 29. Plastic liner constructed for Parshall flume to be placed in open conduit. (*General Signal Corp.*)

solids and debris. Because of its accuracy, nonclogging design, and desirable head-versus-flow characteristics, the Kennison nozzle is well suited for the measurement of raw sewage, raw and digested sludge, final effluent, and trade wastes. Capacities range from 0.13 to 20 million gallons (4921 to 757,000 hectoliters) per day. The unobstructed flow path (with a self-scouring action) prevents clogging by debris.

FLOW STRESS. The instantaneous true tensile stress required to cause continued plastic deformation at a given value of the strain.

FLOW STRUCTURE. A type of banding in effusive igneous rocks (lavas) due to the alignment of minerals, inclusions or gas cavities during the movement of the still molten but viscous material. It is not to be confused with foliation.

FLUCTUATION. In thermodynamics, one deals with matter in bulk, and hence, usually considers uniform systems. However, all matter is built up of atoms, and its atomistic nature will produce fluctuations, which can be studied by statistical means.

For most physical quantities, a system consisting of a large number of particles will show a Gaussian or normal distribution, and the relative fluctuations of a quantity G will usually be given by an equation of the type

$$\frac{\langle G^2\rangle - \langle G\rangle^2}{\langle G\rangle 2} = \frac{1}{\langle G\rangle} \tag{1}$$

where the $\langle\rangle$ indicate average values. As most $\langle G\rangle$ will be proportional to the number of particles in the system, the relative fluctuations will usually be negligibly small.

There are, however, cases where fluctuations become experimentally observable. The first case is that of Brownian movement, where small particles in suspension will undergo fluctuations in the uniform pressure and hence show a random walk phenomenon. The second case is where Equation (1) breaks down. This will happen near a critical temperature when, for instance, critical opalescence occurs.

If we are dealing with systems of bosons or fermions, the equation must be slightly changed, but the conclusion that the left-hand side is usually very small for systems consisting of many particles remains valid.

FLUCTUATION NOISE. Random noise which has a uniform energy versus frequency distribution. Examples are thermal noise and shot noise.

FLUID AND FLUID FLOW. The word fluid refers to a state of matter in which only a uniform isotropic pressure can be supported without indefinite distortion; so, a gas or a liquid. The distinction between highly viscous liquids and solids is a difficult one, the same material acting as an ordinary liquid under some circumstances and as a solid under others. Fluids may be described in various ways. A *perfect fluid* is frictionless offering no resistance to flow except through inertial reaction. A *homogeneous fluid* has the same properties at all points. An *isotropic fluid* has local properties that are independent of rotation of the axis of reference along which those properties are measured. An *incompressible fluid* is a fluid whose density is substantially unaffected by change of pressure. The behavior of a real fluid is similar to that of an incompressible fluid only if the pressure variations in the flow are small compared with the bulk modulus of elasticity. For a fluid in motion in a gravitational field with velocities of order v, it is necessary that both v and $\sqrt{gh}$ should be small compared with the velocity of sound in the fluid. (h is the depth of the fluid and g the acceleration due to gravity.) An *elastic fluid* is a fluid for which elastic stresses and hydrostatic pressures are large compared with viscous stresses. A *viscous fluid* has an appreciable fluid friction. A *Newtonian fluid* is a viscous fluid in which the viscous stresses are a multiple of the rate of strain. The contact of proportionality is the fluid *viscosity*. A *Maxwellian fluid* is a viscous fluid in which the stress-strain relationship includes the relaxation effect (which takes a measurable time) of the relaxation of the elastic stresses set up by a sudden deformation. A *thixotropic fluid* is a fluid whose viscosity is a function not only of the

shearing stress, but also of the previous history of motion within the fluid. The viscosity usually decreases with the length of time the fluid has been in motion. Such systems commonly are concentrated solutions of substances of high molecular weight, or colloidal suspensions. See also **Viscosity**.

Fluidity is the property of a substance that expresses its ability to *flow*, as contrasted with viscosity, which is the resistance to flow. Fluidity is a measure of the rate at which a fluid is deformed by a shearing stress, and is mathematically the reciprocal of the viscosity.

Fluid Dynamics

The study of the motion of matter in the gas, liquid, plastic, or plasma state is *fluid dynamics*. When restricted to the flow of incompressible (i.e., constant density) fluids, the term *hydrodynamics* is used. When dealing with electrically conducting fluids with magnet fields present, the term *magneto-fluid dynamics* is used. When dealing with practical problems of air flow past airplane wings, through ventilating equipment, etc., the term *aerodynamics* is used. See also **Aerodynamics**.

Basically, two fundamental approaches are used: (1) continuum or field dynamics and (2) kinetic theory and nonequilibrium statistical mechanics. The study of fluids tends to be quite complex.

Continuum Dynamics. In this approach, fluid properties, such as velocity, density, pressure, temperature, viscosity, and conductivity, among others, are assumed to be physically meaningful functions of three spatial variables x_1, x_2, and x_3, and time t. Nonlinear partial differential equations are set up to relate these variables. Such equations have no general solutions even for the most restrictive boundary conditions. But solutions are carried out for very idealized flows. Couette flow is one of these. See Fig. 1.

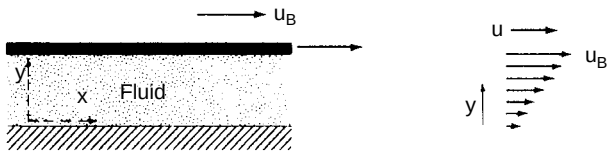

Fig. 1. Couette flow.

The flow is between parallel plates, lower plate at $y = 0$ at rest. upper plate y_B moving with constant speed u_B in the x direction. Stress throughout the fluid is constant, given by $P_{xy} = \mu(du/dy) = \mu(u_B/y_B)$. This is pure shear flow and experimentally is often considered to define and measure the viscosity coefficient μ, assumed constant for the homogeneous fluid. The velocity profile appearing at the right in Fig. 1 shows by velocity arrows of different length at the various positions of y how the velocity varies with position. Steady flow (no dependence of any quantity on time), constant pressure, constant density, and laminar flow are additional assumptions for Couette flow. The flow is realized experimentally by confining the fluid in the narrow annulus between rotating concentric cylinders of nearly equal radius; the cylinders rotate at different speeds.

In Fig. 2, the special flow (Poiseuille flow) is in a pipe of uniform cross section, pressure is assumed to be constant across each cross section but to vary linearly with distance x along the axis of the pipe so that $dp/dx = (p_1 - p_2)L$. Pistons driving the flow are assumed to be infinitely far away, so that the flow velocity, parallel to pipe axis, has the same dependence upon y and z for all x. The velocity profile is parabolic in both the two-dimensional case (infinite parallel plates) and in the circular cross-section case. Mean flow velocity u_m and viscosity coefficient are assumed constant: the flow is assumed steady and laminar. For a circular cross-section pipe of radius α, at any distance r from the center. $u = 2u_m(1 - r^2/a^2)$, and the volume passing a cross section per second is $Q = \pi a^2 u_m = \pi a^4(p_1 - p_2)/8\mu L$. Since these formulas do not apply near pipe entrances, discretion in applying them to pipes of finite length is necessary even when the flow is steady and laminar. See also **Laminar Flow**; and **Turbulent Flow**.

Other examples of idealized solutions are: one-dimensional flow of an ideal gas through a normal shock wave; flow of an ideal gas without viscosity through a pipe of slowly changing cross section (wind tunnel); and one-dimensional finite waves in an ideal gas. Numerous other solutions involve making whatever approximations and assumptions necessary to obtain descriptions of observed flows.

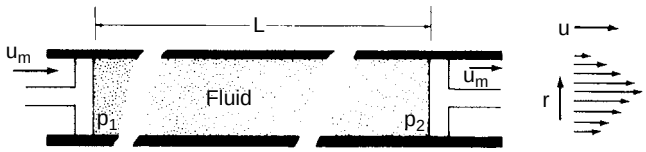

Fig. 2. Poiseuille flow.

Kinetic Theory. In the kinetic theory and nonequilibrium statistical mechanics, fluid properties are associated with averages of properties of microscopic entities. Density, for example, is the average number of molecules per unit volume, times the mass per molecule. While much of the molecular theory in fluid dynamics aims to interpret processes already adequately described by the continuum approach, additional properties and processes are presented. The distribution of molecular velocities (i.e., how many molecules have each particular velocity), time-dependent adjustments of internal molecular motions, and momentum and energy transfer processes at boundaries are examples.

When motion of the fluid consists of only small fluctuations about a state of near-rest, the continuum equations are linearized by neglecting nonlinear terms; and they become the equations of acoustics. A large variety of fluid motions are described as sound waves; when the small-motion or acoustic description can be used, the principle of superposition is valid. This powerful principle allows addition of simple simultaneous motions to represent a more complex motion, such as the sound reaching the audience from the instruments of a symphony orchestra. The superposition principle does not apply to large-scale (nonacoustical) motions, and the subject of fluid dynamics (in distinction from acoustics) treats nonlinear flows, i.e., those that cannot be described as superpositions of other flows. See also **Superposition (Principle of)**.

Since sound waves travel with a speed relative to the fluid, waves moving in a moving field can sometimes be carried off in a direction opposite to the direction of sound travel. The flow where this occurs is called *supersonic*; the flow speed is greater than the sound speed at the spot where the flow is supersonic. Supersonic flow occurs around high-speed vehicles and missiles, and in pipes when high pressure gas escapes through a nozzle into a region of sufficiently lower pressure. A steady supersonic flow always must pass through a *shock front* to slow down to subsonic flow again.

The continuum description of flow fails to describe nearly all actual flow because actual flows when looked at carefully are *turbulent*. Turbulent flows have violent and erratic fluctuations of velocity and pressure not associated with any corresponding fluctuations of the boundaries containing or driving the fluid. Turbulence is generally considered to be the manifestation of the nonlinear nature of the fundamental equations. Under certain conditions, nonturbulent or *laminar* flow exists. A common example is cigarette smoke rising from a cigarette held at rest; near the cigarette, the stream is smooth and straight, or laminar, and further up the flow breaks into turbulence. See also **Reynolds Number**.

Flowing Fluids

Fluids exhibit a number of specific characteristics when they are caused to flow, as contrasted with remaining at rest.

Conservation Laws. The fundamental conservation laws of physics can be used to obtain the basic equations of fluid motion, the equations of continuity (mass conservation), of flow (momentum conservation), of energy (first law of thermodynamics). In addition, conservation over the whole flow system imposes constraints on the flow that can be very useful. The best known of these is the *Kárman momentum integral* for nearly unidirectional mean flow,

$$\frac{d}{dx}\int \rho v(v_1 - v)\, dy - \frac{dP}{dx}\int \frac{(v_1 - v)}{v_1} dy = [\tau]$$

equating the momentum flux by flow to the total forces applied by pressure gradients and boundary stresses. See also **Bernoulli Law**.

Fluid Dynamic Pressure. The pressure necessary to accelerate a fluid from rest to a speed of V is the dynamic pressure equivalent to that speed. If p is taken as mass density of the fluid,

$$\text{dynamic pressure, } q = \frac{\rho V^2}{2}$$

This conception is useful in aerodynamics as the dynamic pressure represents the unit air pressure acting on a surface increment in atmospheric air moving with velocity V over the surface. By Bernoulli's theorem,

$$p = p_0 - \frac{\rho v^2}{2} p_0 - q$$

The vacuum caused by air in motion over a surface is greatest when this imaginary dynamic pressure is greatest since q represents the vacuum.

Fluid Dynamical Similarity. Two geometrically similar fluid flows are dynamically similar if the flow field of one may be transformed into the flow field of the other by the same change of length and velocity scales that was necessary to make the boundary conditions identical. If the equations of motion of the flow are made nondimensional by expressing velocities and lengths as fractions of these scales, these equations contain a number of nondimensional coefficients that determine the character of the flow. The general condition for dynamical similarity is that all these coefficients should be the same for the two flows. For geometrically similar flows, the conditions to be observed are generally expressed as the Reynolds number, the Prandtl number, the Grashof (or Rayleigh) number, the Mach number, and the Froude number. See also **Froude Number**; **Grashof Number**; **Prandtl Number**; and **Rayleigh Number**.

Boundary Layer in Flowing Fluids. Motion of a fluid of low viscosity, such as air or water, around a stationary body or through a stationary conduit, possesses the free velocity of an ideal fluid everywhere except in an extremely thin layer immediately next to the stationary body.

Many of the phenomena of fluid flow may be studied and analyzed without consideration of this boundary layer. But, thin as this layer may be [usually a few thousandths of an inch (less than a millimeter)], its internal mechanics must be understood and evaluated in certain of the phenomena of fluid motion. Some of the more important of these considerations are:

1. The magnitude of the maximum lift coefficient of the airfoils.
2. Profile drag of airfoils.
3. The drag of bluff bodies.
4. The large variations of drag coefficient at critical Reynolds number for laminar-turbulent transition.
5. The transfer of heat through surface films.

Many of the phenomena of the boundary layer are explainable on the basis of the theory advanced by Prandtl at the University of Göttingen laboratory nearly half a century ago. In the same flow-research group were others, like Blasius, who broadened and experimentally confirmed the original hypotheses.

An elementary understanding of the effect of fluid viscosity will be had by considering a two-dimensional flow along the upper surface of a very thin flat-plate, as shown in Fig. 3. The thickness of the boundary layer, greatly exaggerated, is y_v; the free stream velocity is V, the variable velocity in the boundary layer is u. A basic assumption of the theory is that a fluid layer of infinitesimal thickness resting against the plate "sticks" to it, so shearing force of the next fluid layer on the stationary layer determines the skin friction. Assuming that the boundary layer consists of lamina of fluid sliding on each other, the velocities of these lamina increase with y until, at the edge of the boundary layer, $u = V$. A series of boundary layer velocity profiles for stations x_1, x_2, x_3 are drawn, to enable the reader to visualize the effect of friction on the momentum in the boundary layer, and the thickening of it due to lower average u.

Note also the variation of the profile near the surface of the plate. Skin friction has steadily decelerated the individual fluid particles. The profile at x_3 indicates that the lower portion has come to rest. This is known as the stagnation point. Air-flow phenomena in this region are important in many ways, especially when there is an intended rising downstream pressure gradient, as in diffuser tubes or over the surface of airfoils.

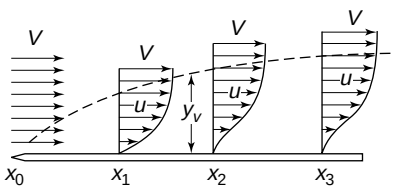

Fig. 3. Velocity profiles in the boundary layer. Dashed line is hypothetical upper edge of the boundary layer.

Fluid flow in a divergent tube is illustrated in Fig. 4. On the lower profile, greatly enlarged velocity profiles are shown for the boundary layer at stations $x_1, x_2, \ldots x_6$. The x_4 profile indicates a stagnation point. Since the pressure gradient of the diffuser has a pressure at x_5 above that at x_4, a reverse flow is produced toward the stagnation point. Streamlines, drawn in the upper half of the tube, show what happens to the fluid flow. The region of the surface of separation between the reverse flow along the wall and the forward flow is unstable and breaks up into random vortices. Kinetic energy is irreversibly transferred to heat and the diffusion fails to produce the expected pressure gradient. Had the divergence of the conduit been sufficiently small, the pressure gradient would have been lowered per unit length and turbulence in free stream or boundary layer would have delayed the stagnation point.

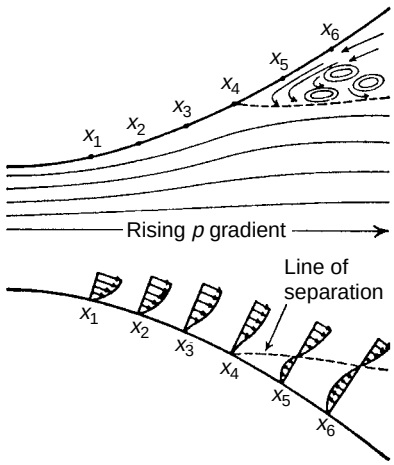

Fig. 4. Effect of boundary layer viscosity of flow on a diffuser.

For the airfoil (Fig. 5) with burbled or partly burbled air flow, a similar explanation exists. Streamline flow over the upper surface of the airfoil increases in velocity as angle of attack (and circulation Γ) increases. However, the surface friction in the boundary layer is decelerating the air particles next to the surface and, with high adverse pressure gradient (existing at high angle of attack) opposing the kinetic energy of the boundary layer, the velocity profiles ultimately show a stagnation point toward the rear of the airfoil. The flow separates from the surface and vortices form a turbulent wake in place of the streamline wake previously existing. Once the separation surface moves onto an airfoil, minor increases of angle of attack bring it rapidly forward. High circulation strength is no longer needed to fulfill the requirement of unity of upper and lower flows at the trailing edge (Kutta's hypothesis) so Γ decreases sharply, and with it the lift. Boundary layer theory accounts in this manner for the maximum lift coefficient. At the same time the extended turbulent wake sharply increases the profile drag coefficient.

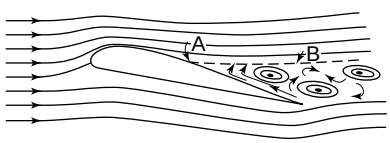

Fig. 5. Partial burble on airfoil at high angle of attack: (**a**) stagnation point; (**b**) line of separation.

Now return to a view of the nature of flow in the boundary layer. It has been called laminar, and so it is for values of the Reynolds number below a *critical* value. But for years, beginning about the time of Osborne Reynolds' experiments and revelations in the field of fluid flow, it has been known that the laminar property disappears, and the flow suddenly becomes turbulent, when the critical Vl/v is reached. Usually flow starts over a surface as laminar but after passing over a suitable length the boundary layer becomes turbulent, with a thin laminar sublayer thought to

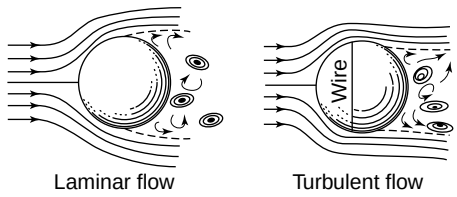

Fig. 6. Boundary layer turbulence reduces width of low-pressure wake.

exist because of damping of normal turbulent components at the surface. See Fig. 6.

This transition has profound effects in all fluid dynamics, and certainly so in aerodynamics. The velocity profile in the boundary layer becomes fuller near the surface on account of the higher average kinetic energy of the layer created by turbulent energy exchange from layer to layer. The effective viscosity is therefore larger in turbulent than laminar flow, the turbulent boundary layer thickens more rapidly downstream, the skin friction increases.

The importance to aerodynamics is the beneficial effect of turbulence on the wake existing in the rear of bluff bodies. Even thin airfoils become bluff bodies at high angles of attack. A turbulent boundary layer has more kinetic energy than a laminar one. This carries the air farther toward the rear of the surface before a stagnation point is reached and so reduced the width of the wake and that part of the profile drag. This reduction of drag can be, and usually is, much larger than the increase of skin friction so turbulence has a good effect on both profile drag and maximum lift coefficient of an airfoil. The critical value of Reynolds number lies between 200,000 and 2,000,000, being affected by the initial turbulence existing in the air prior to meeting the surface. Decreasing initial turbulence increases the critical Reynolds number. The effect of turbulence on the boundary layer is strikingly displayed by observing the drag wake behind a smooth sphere mounted in an airstream whose velocity is just under that required to produce breakdown of the laminar boundary layer. An artificial roughness is provided in the form of a fine wire or thread encircling the sphere in the laminar flow. The boundary layer, of course, becomes turbulent downstream from this irregularity resulting in a delayed stagnation point and narrower wake.

See also **Aerodynamics**.

Constant-Stress Layer in Flowing Fluids. In the boundary layer of a fluid flowing over a solid wall, the shear stress varies with distance from the wall but it may be considered nearly constant within a small fraction of the layer thickness. The concept is of particular importance in turbulent flow where it leads to a theoretical derivation of the "law of the wall," the logarithmic distribution of mean velocity. The constant stress layer is the best-known example of the equilibrium flows near a wall.

Classes of Flowing Fluids

Just as there are many types of fluids, so there are, partly as a result, many types of fluid flow. *Uniform flow* is steady in time, or the same at all points in space. Steady flow is flow of which the velocity at a point fixed with respect to a fixed system of coordinates is independent of time. Many common types of flow can be made steady by a suitable choice of coordinates. *Rotational flows* have appreciable vorticity, and they cannot be described mathematically by a velocity potential function. *Turbulent flow* is flow in which the fluid velocity at a fixed point fluctuates with time in a nearly random way. The motion is essentially rotational, and is characterized by rates of momentum and mass transfer considerably larger than in the corresponding laminar flow. *Laminar flow* is flow in which the mass of fluid may be considered as advancing in separate laminae (sheets), with simple shear existing at the surface of contact of laminae, should there be any difference in mean speed of the separate laminae. If turbulence exists, its effect is confined to a lamina, and there is not exchange of momentum between laminae. *Streamline flow* is flow in which fluid particles move along the streamlines. This motion is characteristic of viscous flow at low Reynolds numbers or of inviscid, irrotational flow. *Secondary flow* is a less rigorously defined term than many of the foregoing types of flow. The flow in pipes and channels is frequently found to possess components at right angles to the axis. These components which take the form of diffuse vortices with axes parallel to the main flow form the secondary flow. Three types may be mentioned: 1. Secondary flow in curved pipes or channels, being a motion outward near the flow center and inwards near the walls. 2. Secondary flow in straight pipes and channels of noncircular section, being a motion along the walls toward corners or places of large curvature and from there to the center of the flow. This only occurs in turbulent flow. 3. Secondary flow in pulsating flow. This is due to second-order effects and is particularly striking with ultrasonic waves.

For many types of flow, calculations are complex. Where they can be made at all, they require the methods of tensor analysis of the stresses and strains involved. One important relationship that is widely useful in the systematic study of fluid flow in the equation of continuity.

A great simplification of the fluid calculations can be effected by assuming that the fluid is perfect, homogeneous, totally incompressible, not viscous, and that therefore its properties are not affected by changes in temperature or pressure. While such an ideal fluid does not exist, its properties are often approached closely enough by real fluids so that calculations based upon it are often useful in practice.

Thus, elementary hydraulics always includes Bernoulli's law, and it is repeated here due to its great importance to the subject of fluid flow.

Bernoulli's law is

$$\frac{p}{w} + \frac{v^2}{2g} + z = \text{a constant}$$

and the symbols are defined as follows:

p = the static pressure in pounds per square feet
w = the specific weight of fluid in pounds per cubic feet
v = the velocity in feet per second
g = the gravitational acceleration in feet per second
z = the potential, or "elevation," head in feet

Bernoulli's law states that in steady flow, the total head is a constant at any point and equal to the sum of the pressure head, p/w, the velocity head, $v^2/2g$, and the potential head (z). Since there is actually a loss of head between any two points due to friction, the difference between the total heads at any two points must equal the friction head when the flow is steady.

In this equation, $v^2/2g$ represents the velocity head, a pressure that could be recovered by the efficient reduction of the velocity in a conduit of expanding cross section. When this velocity head is multiplied by the specific weight of the fluid, it is reduced dimensionally to the unit of pressure, pounds per square feet. It may be designated the dynamic pressure, in counter distinction to the static pressure p. In the case of an expansionable fluid, such as gas, the total energy at two points in the flow must be the same, that is, the heat energy, plus the kinetic energy of motion, must be constant. It is necessary to invoke this law of continuity of energy in dealing with the flow of gases or vapors through nozzles. See also **Viscosity**.

FLUID FRICTION. The flow of any actual fluid must of necessity be attended by the presence of friction, due to the physical nature of fluids, none of which meets the requirements of the ideal fluid, as mentioned in fluid flow. A great deal of time and attention have been devoted to the

study of the properties of a flowing fluid. The frictional effects present in the flow of liquids have been rationalized much more thoroughly than for vapors and gases. However, for all three the friction is found to depend upon the nature of the fluid itself, its viscosity, and upon the conduit which contains it. Due to the different molecular arrangement of liquids, vapors, and gases, the study of friction of fluids has become a specialized study of each of these three.

Fluid flow rarely follows the commonly accepted idea of streamlines, since the velocities necessary for viscous flow of this nature are almost always lower than those found expedient to employ. Most flows are turbulent in nature. They become turbulent at a definite velocity, the value of which was studied by Reynolds; and this value is incorporated in the well-known Reynolds Number. A general thermodynamic equation of energy of a fluid under flow conditions would be as follows:

Gain in kinetic energy + gain in potential energy + network received + energy liberated by any chemical change = change in heat content between two states.

In the case of a liquid, this equation can be considerably simplified — in fact, it becomes Bernoulli's well-known equation — but in the case of compressible fluids, which may also undergo some change of form, such as condensation or compression, the longer equation applies. Most practical problems in fluid friction arise in connection with the flow of fluid through pipes.

FLUIDICS. The technology of sensing, controlling, and information processing with devices that use a fluid medium, and whose operation is based solely upon the interaction between fluid streams. The particular function of each device, none of which has moving parts, is dependent upon the geometric shape of the device.

Fluidics is considered to have commenced in 1959 with the work of B.M. Horton, R.E. Bowles, and R. Warren, scientists at the Diamond Ordnance Fuze Laboratories (U.S. Army), Washington, D.C. Some of the principles employed in fluidics involve earlier discoveries by scientists, such as Henri Coanda, a Rumanian engineer who, in 1926, identified the wall-attachment phenomenon for fluid jets — a principle which is now known as the Coanda effect.

Fluidic principles have been applied in the construction of amplifiers, oscillators, computing and logic elements; analog controllers; flowmeters; temperature proximity and dimensional gaging sensors; process control valves; and level controllers.

Characteristics. The major characteristics of fluidic devices include:

(1) *No moving parts* — The absence of moving parts provides fluidic devices with a potential for high reliability.

(2) *Use any fluid* — Almost any gas, liquid, or slurry may be utilized in fluidic devices.

(3) *High amplification* — A high-energy stream is controlled by a low-energy stream. Gains as high as 1,000 or more have been achieved.

(4) *No practical size limitation* — Fluidic devices can be built in practically any size. There is no reasonable limit, for example, as to how large a process control valve can be. Conversely, miniaturized elements have fluid passageways on the order of 0.010 inch (0.254 millimeter).

(5) *Wide choice of construction materials* — Almost any material that can be cast, molded, machined, formed, or etched can be used to construct a fluidic device.

(6) *High response speeds* — Oscillators have been made to operate at frequencies of 10,000 Hz. The flow in a large 4-inch (10.2-centimeter) liquid-diverting valve can be switched completely in 0.1 second.

(7) *No shock or water hammer* — Even though switching occurs at high speed, there is no shock or water hammer involved when a liquid fluidic diverting valve is switched.

(8) *Unaffected by environment* — Since fluidic devices can be built of nearly any material, the devices can operate under extremes of temperature, vibration, and radiation. Also, operation is unaffected by electricity and magnetism.

Principle of Operation. The simplest form of fluidic amplifier (Fig. 1) uses cross-directed fluid jets. The main jet can be deflected in proportion to the strength of a cross-directed control jet. If receiving apertures are placed downstream, the deflection manifests itself as a relative change in flow and pressure at the apertures. This type of amplifier works entirely on the momentum-exchange principle. However, because so much energy is lost due to turbulence, such a device is quite inefficient.

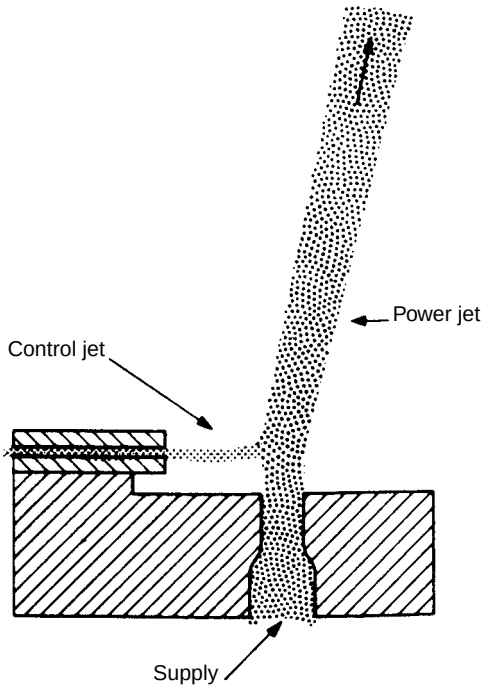

Fig. 1. Basic fluidic amplifier.

An additional principle employed in most fluidic devices is the Coanda effect, sometimes referred to as the wall-attachment principle. To illustrate this principle, assume a device has a cross section as shown in Fig. 2 and plates top and bottom so that the downstream end and left side are open. An end view is shown in the figure. Assume this device is operating open to atmosphere and that compressed air is supplied to the power nozzle. At the moment when supply air is turned on, the main jet tends to project in a straight line [Fig. 2(**a**)]. Note that the jet, being rectangular in cross section, seals against the top and bottom plates and has the effect of a barrier or movable wall running parallel to the side wall. Whenever a jet flows into a body of stagnant fluid, it entrains some of the surrounding stagnant fluid and starts it into motion. In this case, as the ambient air is entrained and ejected along both sides of the main jet, replenishing air continuously moves into this region. Along the open wall, the replenishing air moves in, unimpeded, and the average pressure along this side is essentially atmospheric. However, along the right side of the jet, the replenishing air must flow down through the restricted opening between the wall and the jet boundary. The average pressure on the wall side, therefore, will be somewhat below atmospheric.

The resultant differential in pressure across the two sides of the jet causes the jet to move closer to the wall, as indicated in Fig. 2(b). This, in turn, further restricts the passage down through which replenishing air must move, making the pressure along the wall decrease further, while the differential across the jet correspondingly increases.

This action is regenerative and continues until it terminates with the jet attached to the wall, as shown in Fig. 2(c). In this condition, a vortex forms in the region between the inside boundary of the jet and the wall. This region is also referred to as a separation bubble. The pressure in this region would be at a high vacuum in the example given, and the jet would remain attached to the wall because of the differential pressure impressed upon it.

To detach the jet from the wall, it would be necessary to supply sufficient replenishing air to the separation bubble. This could be done by supplying the air through a control port, as will be shown in succeeding examples.

The main jet and the ambient fluid in this example need not have been air. These principles apply even if the jet and ambient fluids are different from air. Likewise, the jet and ambient fluids can be different from each other. In fluidic control valves, for example, it is common to control a liquid jet by means of ambient air. The Coanda effect, therefore, is the basis for the "memory" function obtainable in these devices; and the positive

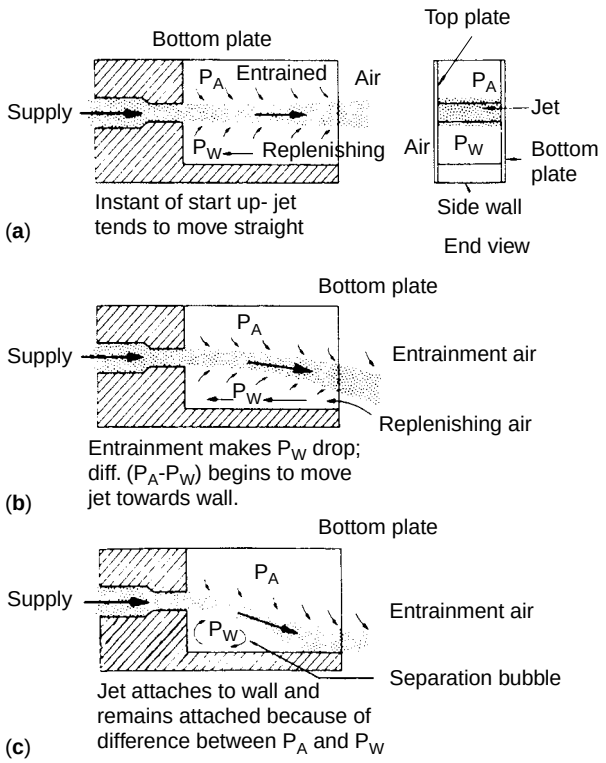

Fig. 2. Demonstration of Coanda effect.

feedback provides results in high amplification and much more efficient operation.

The technology of fluidics has been applied in a relatively limited number of practical devices, including a fluidic bistable amplifier, a fluidic oscillator, a fluidic pulse counter, a vortex amplifier, and a liquid-diverting valve.

C.L. MAMZIC, Moore Products Co., Spring House, PA

FLUIDIZATION. This term is used in engineering to denote the preparation of a solid material having a particle size and other properties such that it may be handled, in many respects, like a fluid. It also refers to the technology of handling the material under such conditions. One of the early developments in this field was pulverized coal; its development received great impetus in its use in catalytic processes in the petroleum industry, and it has since been extended far more widely. One great advantage of having a solid catalyst that flows like a liquid is that its particle size can be much smaller than possible in the old type of solid-bed catalyst, where entrainment in the passing fluid was objectionable. This smaller particle size greatly increases the surface area (which increases as the inverse square of the particle radius) and therefore increases the effectiveness of the catalyst. Another advantage of fluidization is greater ease and hence lower cost of handling, which has permitted the use of catalysts in processes that require their frequent reactivation.

Other applications of fluidization have been made to such materials as sodium chloride (table salt), soda ash, sodium phosphate, sodium sulfate, starch, talc, magnesium oxide, dry clay, boric acid, hydrated lime, and various high polymers in powdered or "bead" form. Fluidization is especially effective in loading and unloading materials from railroad cars and trucks, as well as in moving them about within the plant.

FLUID MECHANICS. Fluid mechanics is both a descriptive science of the phenomena that occur when fluids flow and a quantitative science showing how these phenomena may be described in mathematical terms and predicted when appropriate conditions are prescribed. To a practicing chemical technologist, fluid mechanics is an entire body of knowledge, theoretical and empirical, qualitative and quantitative, allowing analysis of the performance of complex plant equipment handling moving fluids. Before being in a position to calculate the details of a flow, one needs to understand the phenomena well enough to model the process properly. At times the technologist's needs are best satisfied by an empirical correlation; at other times the necessary skills consist largely of knowing how to apply the idealized mathematical solutions to a practical situation. See also **Flow Measurement (Liquids and Gases)**; **Fluid and Fluid Flow**; and **Fluidization**.

FLUID PARCEL. In any fluid, an imaginary portion of that fluid which for theoretical studies may be considered to have all the basic dynamic and thermodynamic properties of the fluid but which is small enough so that its motion with respect to the surrounding fluid does not induce marked compensatory movements. Also called *parcel*. The size of the fluid parcel cannot be given precise numerical definition but it must be large enough to contain a great number of molecules and small enough so that the properties assigned to it are approximately uniform within it. See also **Fluid and Fluid Flow**.

FLUKE. 1. A parasitic flatworm. *Trematoda*. These worms attack many species of animals, passing through a complicated life cycle involving two or three hosts. The liver-fluke of the sheep, which spends part of its life in the body of a snail and becomes adult in the liver of the sheep, is a well-known example. A number of species attack man, particularly in the Orient and in warmer countries. They fall into four groups, the liver, lung, blood and intestinal flukes, depending on the part of the body in which they thrive.

2. The broad horizontal lobes of the whale's tail.

3. Fish, *Platichthys flesus* and *Paralichthys dentatus*, belonging to the flatfish family.

FLUME. An open channel for conveying water for some special purpose, such as water power, washing, etc., is a flume. Flumes are frequently constructed of lumber having the boards placed in the direction parallel to the flow, these often being planed on the wetted side. However, flumes are also constructed of concrete, brick, etc. The flow in a flume is created by the slope of the bottom, releasing a certain amount of energy of position. This is converted into energy represented in the friction between the water and the flume, provided the flow in the flume is uniform.

Specially designed flumes are also used in connection with the measurement of flow in open channels. *Parshall* flumes have been constructed in sizes with throat widths ranging from 3 inches to 40 feet (7.6 centimeters to 12 meters) for measuring flows up to 1,500 million gallons (56.8 million hectoliters) per day. The flume operates essentially on the principle of the weir wherein the height of the level of the flowing medium in the device is a measure of the flowing volume. See also **Flow Measurement (Liquids and Gases)**.

FLUORESCEIN ANGIOGRAPHY. Angiography is a diagnostic test used by ophthalmologists to photograph structures in the back of the eye and is especially useful in finding damage to the blood vessels, that nourish the retina. There are two types of angiography: fluorescein and indocyanine green (ICG). Fluorescein angiography is used primarily to study blood circulation in and just beneath the surface of the retina. ICG angiography is better for photographing the deeper choroidal vessels.

The purpose of either type of angiography is to determine whether there are irregularities in the circulatory system of the retina. Several serious eye disorders, such as diabetic retinopathy, affect retinal circulation and are usually studied with the fluorescein procedure. Other problems, such as age-related macular degeneration, are caused by leakage from the deeper choroidal blood vessels. In these cases, the ICG procedure can provide additional information, which may not be available through a fluorescein angiography.

In both angiography procedures, a small amount of colored dye is injected into a vein in the arm where it travels through the circulatory system and into the vessels in the eye. The dye makes these vessels visible

to a special camera that is used to take photographs used by the doctor to diagnose various disorders of the eye.

In fluorescein angiography, a small amount of vegetable-based dye (sodium fluorescein which is either orange or yellow in color) is injected into an arm vein. The dye travels through the circulatory system and, in about 15 seconds, reaches the blood vessels in the retina and the choroid, the major blood vessel of the eye lying between the retina and the sclera.

During a period of 2 to 5 seconds, the dye travels through the capillaries and fills the veins. Rapid, sequential black and white photographs, taken as the dye circulates, document how the dye enters the different blood vessels. Diseases of the retina, choroid, and retinal blood vessels will interrupt the progression of dye. Depending on the specific problem, another set of photographs may be taken about 15 minutes later in order to show staining that can possibly indicate leakage or swelling on the retina. These photographs will detect any abnormalities in the retina that are not visible by other procedures.

Fluorescein angiography takes about 20 to 30 minutes and is virtually painless. After the test is complete, the pupils may remain dilated for several hours, so it is a good idea to arrange for another person to provide your transportation home.

As in fluorescein angiography, ICG angiography requires the injection of dye into a vein in the arm. The dye travels through the circulatory system and reaches the blood vessels in the retina and the choroid. The difference between fluorescein and ICG angiography is primarily in the type of dye that is used. The green ICG dye glows or "fluoresces" and, unlike the dye used in the fluorescein procedure, allows the camera to see through blood, fluid, and pigments that obscure certain conditions from view. The fluorescing quality of the ICG dye also allows special digital cameras to capture and view images as the test is being done.

ICG is especially helpful in situations where the source of leakage may be obscured by a hemorrhage of the retina, which makes interpretation of fluorescein studies difficult. To date, the most useful application of the ICG procedure is the diagnosis and treatment of age-related macular degeneration, the leading cause of new blindness in people over the age of 55 in this country. Precise application of a laser is critical to the treatment of the more serious (wet) form of this disease. The ICG angiography often enables the ophthalmologist to do a better job of pinpointing the location of the leakage.

Side effects from either angiography procedure are minimal. The dye used in fluorescein angiography sometimes causes temporary, harmless discoloration of the skin and urine, and a small percentage of patients may feel slightly nauseated for a short time during the initial phase of the procedure. Allergic reactions to the ICG dye are rare. However, patients allergic to iodine or shellfish, or those with a history of liver disease, should advise their physician. See also **Age-Related Macular Degeneration**; **Diabetic Retinopathy**; and **Retina**.

Vision Rx, Inc., Elmsford, NY

FLUORESCENCE. This term has three common usages: 1. The process of emission of electromagnetic radiation by a substance resulting from of the absorption of energy from radiation. This energy may be either electromagnetic or particulate, provided that the emission continues only as long as the stimulus producing it is maintained. That is, fluorescence is a luminescence which ceases within about 10^{-8} second after excitation stops; this period of time being the lifetime of an atomic state for a normal allowed transition.

2. The term fluorescence may also be applied to the radiation emitted, as well as to the emission process.

3. In X-ray terminology, the term fluorescence may be used in the more specific sense (than given in the general definition above) to denote the characteristic X-rays emitted as a result of the absorption of X-rays of higher frequency.

FLUORESCENCE YIELD. The probability that an atom whose electronic structure has been excited will emit an X-ray photon, in the first transition, rather than an Auger electron. The value of the fluorescence yield lies between 0 and 1, characteristic of the particular state of excitation of an atom of a particular element. The K-shell fluorescence yield increases with increasing atomic number, and is the sum of the $K \rightarrow L_{II}$, $K \rightarrow L_{III} \ldots$ transitions.

FLUORESCENT SCREEN. A plate coated with a material readily fluorescent. It is used to observe certain patterns or other properties of invisible radiations, such as X-rays, from the fluorescent radiations emitted by the screen. It is also used to form the visible image in cathode-ray tubes as used in oscilloscopes and television tubes.

The distinction between fluorescent and phosphorescent screens is frequently not clearly defined. Fluorescent screens are properly those with only a very short glow-period after the exciting radiation (or electron beam) is extinguished.

FLUORINE. [CAS:7782-41-4] Chemical element symbol F, at. no. 9, at. wt. 18.9984, periodic table group 17 (halogens), mp $-219.62\,^{\circ}C$, bp $-188.1\,^{\circ}C$, density 1.696 g/l (gas at $0\,^{\circ}C$), 1.108 g/cm^3 (liquid at bp). Fluorine is a pale yellow gas, poisonous, very reactive, combines with most other elements in the dark, except it does not combine readily with oxygen. Critical pressure is 55 atm; critical temperature is $-129.2\,^{\circ}C$. First identified by Scheele in 1771, but not isolated until 1886 by Moissan who electrolyzed fused potassium hydrogen fluoride in a platinum apparatus. Fluorine is a high-tonnage chemical, used mainly in the production of fluorides, in the synthesis of fluorocarbons, and as an oxidizer for rocket fuel.

First ionization potential 17.42 eV; second, 34.6 eV; third, 58.02 eV; fourth, 84.88 eV; fifth, 113.0 eV; sixth, 152.9 eV. Oxidation potential $F^- \rightarrow \frac{1}{2}F_2 + e^-$, -2.85 V; $2\,F^- + H_2O \rightarrow F_2O + 2\,H^+ + 4\,e^-$, 2.1 V; $HF \rightarrow \frac{1}{2}F_2 + H^+ + e^-$, 3.03 V. Other important physical characteristics of fluorine are given under **Chemical Elements**.

Production. Because fluorine is the most reactive element and one of the strongest oxidizing agents known, its preparation caused difficulties for many years. The requirements for fluorine, for separating ^{235}U from ^{238}U during the development of the atomic bomb, accelerated research on finding improved production methods. Much research went into the development of compounds and materials that would resist the actions of fluorine for use in diffusion plants. Materials finally selected and in use in modern fluorine production plants include (1) a cathode integral with a mild-steel cell body, (2) a carbon anode, (3) a steel cell head, including a Monel skirt, and (4) a Monel screen diaphragm. The skirt is required to prevent admixture of the fluorine gas formed with the hydrogen gas also formed. The electrolyte consists of a fused mixture of potassium fluoride and hydrofluoric acid. The overall reaction: $2\,HF \rightarrow H_2 + F_2$. Hydrogen is liberated at the cathode; fluorine at the anode. The potassium fluoride is required because hydrofluoric acid of the purity required does not conduct an electric current.

Fluorine causes both chemical and thermal burns and, unfortunately, they may not be detected immediately, depending upon the concentration. Further, upon contact with the skin, fluorine gas reacts with water in the skin to form hydrofluoric acid, an excellent solvent for protein. Personnel directly involved in the handling of fluorine must be equipped with gauntlet gloves, neoprene rubber apron, chemical goggles and when in atmospheres above the TLV, gas masks with cannisters must be used. In emergency situations where there is a very high concentration of fluorine, the area must be evacuated, directing personnel upwind.

All containers, processing equipment, and piping to be used in fluorine service first must be passivated before use and thereafter designated for fluorine service. These requirements result from the severe oxidizing characteristics of fluorine gas. Passivation removes any easily oxidized materials, such as paint, pipe dopes, metal oxides, grease, and metal filings. During the procedure, a metal fluoride film will form on metal surfaces, thus minimizing further corrosion of the metal by fluorine.

Special permits are required to ship fluorine. Generally, fluorine is transported as a nonliquefied compressed gas in seamless steel or nickel cylinders. Upon receipt, multijacketed dewars frequently are used to contain the product.

Chemistry and Compounds. Fluorine exhibits in common with the other halogen elements a marked readiness to form singly charged negative ions, as would be expected from the fact that these atoms need only one electron to acquire an inert gas configuration. However, the electron affinity of fluorine (3.74 eV) is not the highest of the four common halogens, but is less than that of chlorine and bromine (4.02 eV and 3.78 eV respectively). The greater reactivity of fluorine in aqueous solution is due to the fact that its lower electron affinity is more than offset by its lower energy of dissociation (38 kcal against 58 kcal for Cl_2 and 46 kcal for Br_2) and the higher energy of hydration (122 kcal for F^- against 89 kcal for Cl^- and 81 kcal for Br^-). The overall result is to give the system $F^- \rightarrow \frac{1}{2}F_2 + e^-$,

the largest negative oxidation potential (−2.85 V) of any simple ion to its element.

The reactions of fluorine have, in general, high temperature coefficients. At low temperatures its reactivity with hydrogen is very slight, but becomes rapid and even violent at higher temperatures and in the presence of impurities. Fluorine reacts with all metals, the vigor of the reaction and the composition of the resulting fluoride depending upon the temperature and the reactivity of the metal. Sulfur, silicon, carbon, and antimony ignite in fluorine; cesium, rubidium, and potassium form trifluorides, which, however, do not contain trivalent cations, while the noble metals react only at very high temperatures. Unlike the three alkali metals mentioned, however, most metals do not form fluorides in exceptional oxidation states, and, in fact, many elements form oxyanions of higher valence than they do fluorocomplexes. Thus manganese forms two fluorides, MnF_2 and MnF_3, and its fluorocomplex ions of highest valence are MnF_6^{2-} and Mnf_5^-; chromium forms four stable fluorides, CrF_2, CrF_3, and CrF_4, and CrF_5 (and possibly CrF_6).

Four binary compounds of fluorine and oxygen have been reported, O_4F_2, O_3F_2, O_2F_2, and OF_2. The polyoxygen difluorides are produced from the elements by action of the silent electric discharge at low pressures, lower temperature favoring higher oxygen content. Dioxygen difluoride is a yellow to orange solid, melting at about −160 °C. It decomposes rapidly at temperatures above −25 °C. The others are even less stable. Oxygen difluoride, OF_2, is prepared by passing fluorine rapidly through weak NaOH solutions or by electrolysis of liquid HF solutions of H_2O or other oxygen compounds. It has an O−F bond distance of 1.4 Å, F−F, 2.22 Å, and FOF angle, about 105°. It reacts with metals to form fluorides and oxygen, with other halides to form fluorides, oxygen, and the other halogens, and with other compounds usually to yield fluorides.

Hydrogen fluoride [CAS:7764-39-3] is the most stable of the hydrogen halides (heat of formation 64 kcal). Its bond moment shows the compound to have a marked covalent character. In the pure state, liquid hydrogen fluoride is slightly more conducting than pure water, and in the anhydrous state it reacts only with the alkali metals, alkaline earth metals (excluding beryllium and magnesium) and with thallium. Liquid HF is an extremely strong acid, having a Hammett acidity function of 10.2 (compared to H_2SO_4 11.3), HCl, hydrobromic and hydriodic acids being essentially unionized in it, although the dielectric constant is comparable to that of water. However, in 0.1 *N* aqueous solution, hydrogen fluoride is only about 15% ionized. A correlative property is the extensive polymerization through hydrogen bonding, various polymers being present. In the vapor state, the degree of polymerization depends upon temperature and pressure, varying from mostly monomer to linear hexamer or even higher polymers, with the ring hexamer being particularly favored. The liquid likewise contains monomer and polymers, the average degree of polymerization being three or four. The units of the polymers undergo very rapid exchange. In aqueous solution there is a strong tendency for fluoride ion to associate with hydrogen fluoride molecules, forming the symmetrical HF_2^- ion. It reacts with metal oxides and hydroxides to produce the fluorides, and with metal ions to produce complex ions, or their salts. It reacts with phosphorus pentoxide to produce complex fluorides, oxyfluorides, and, on continued action, mono-, di- or hexafluorophosphates. See also **Hydrofluoric Acid**.

Due to the high oxidation potential of fluorine, and the small size of the fluoride ion, the element enters into many compounds with the other halogens. Diatomic compounds of this type include ClF, BrF, and IF (the latter two having been identified but not isolated in a pure state); tetratomic compounds include ClF_3, BrF_3, and IF_3. Hexatomic compounds include BrF_5, and IF_5, while the octatomic type is limited to one member, IF_7. These compounds are discussed under the entry for the halogen forming the donor atom in the compound.

Fluorine forms polyhalide anionic complexes including $IFBr^-$, $IFCl_3^-$, BrF_4^-, and IF_6^-, which occur in salts of the higher alkalies, as well as cations such as BrF_2^+, which occurs in such salts as BrF_2SbF_6, BrF_2AuF_4, BrF_2SO_3F, etc. The difluoriodate ion, $IO_2F_2^-$ is also known in such salts as KIO_2F_2.

Organic compounds: Organic fluorine compounds are made by reaction of the corresponding alkane chloro-compounds with silver fluoride, mercurous fluoride, antimony trifluoride, titanium tetrafluoride, and the arene fluoro-compounds by the diazo-reaction using hydrogen fluoride, and otherwise. The effect of the continued replacement of hydrogen atoms by fluorine atoms is an initial increase in reactivity, followed by a reversal of this effect, so that the highly substituted compounds are relatively inert. See also **Fluorocarbon**.

Biological Aspects of Fluorine. Fluorides are not required for plant growth, but in animals, including humans, low levels of fluorides have been shown to have beneficial effects on teeth and on bone structure. Growth increases in experimental animals have been reported, when low levels of fluorides have been added to purified diets. However, fluoride substances show toxicity in both animals and plants when encountered in fumes and dusts from industrial facilities as well as natural emissions from the eruption of volcanoes. Abnormally high levels of fluoride in water also have caused fluorine toxicity in animals and mottled teeth in humans.

Fluorides do not usually move from the soil to plants and on to livestock feedstuffs and human foodstuffs in amounts that are toxic. Injury to plants from fluoride in the soil has been noted on soils that are too acid for the satisfactory growth of most plants. On limed soils or soils with sufficient calcium for optimum growth, any fluorine added to the soil reacts with the calcium and other soil constituents to form insoluble compounds, which are not taken up by the plants. Rock phosphate and some kinds of superphosphate fertilizers contain large amounts of calcium fluoride, but the fluorine content of the plants grown on soils that have been heavily fertilized with these phosphates is not appreciably increased. Tea and some other members of the *Theaceae* family are the only plants that take up very much fluorine from the soil.

While the soil-to-plant segment of the food chain contains some built-in safeguards against fluorine toxicity, this toxicity occurs as a result of the deposition of airborne fumes and dusts on the above-ground parts of plants, followed by the consumption of these contaminated plants by animals, including humans. Also, fluorine toxicity has been caused by direct inhalation of the fumes and dusts, or by drinking water with abnormally high fluorine levels. If the fumes and dusts are mixed into the soil, they will be inactivated, and they will not find their way into the food chain in toxic amounts.

The safeguards against toxicity provided by the chemistry of fluorine in soils make it unlikely that applying fluorine-containing compounds to soils will be a useful way to insure that plants will contain sufficient fluorine to prevent dental caries. However, tea and mechanically deboned meats may contribute to these needs. When increased fluoride intake is desirable, *carefully controlled* direct additions to drinking water, to dentrifrices, or to specific foods are more promising than adding fluorides to soils that produce food crops.

Fluoridation. In a broad sense, this term would signify the addition of fluorine to a substance much as chlorination means the addition of chlorine. In a more specific, but commonly used sense, fluoridation means the addition of very small amounts of a fluoride-containing compound to water supplies for the purpose of preventing dental caries. It has been shown over a number of years that the introduction of about 1 part per million (ppm) of fluoride to drinking water will reduce the incidence of tooth decay in children by as much as 60%, as compared with similar groups of children who consume nonfluoridated water. Because of the striking nature of these findings, a few cities in the United States commenced experimental treatment of water supplies during the mid-1940s. As of the early 1980s, it was estimated that nearly 100 million persons in the United States were supplied with fluoridated water.

The commonly used compound is sodium fluoride or sodium silicofluoride in a dry crystalline or powdered form. Hydrofluosilicic (flusilicic) acid is also used in liquid form. Inasmuch as concentrations of fluoride in excess of 1.5 ppm may cause mottling of tooth enamel, it is mandatory to exercise very careful control to maintain the desired 1.0 ppm dosage. Water supply samples are frequently tested by municipal authorities. Fluoride concentrations may be determined by colorimetric or electrometric methods, and the latter can be adapted to continuous reporting and controlling.

The concept of fluoridation has created numerous controversies among the populace, a situation that occurs frequently when decisions to install fluoridation systems for the first time are under consideration. Until the mid-70s, it was believed that such practice was unquestionably safe and that arguments against fluoridation were essentially emotionally motivated. However, some second thoughts are now being taken, particularly with reference to possible reactions of fluorine with certain pollutants now found in raw water supplies that once were not present.

Feedstuffs. Excessive amounts of fluoride in the soil can cause tooth and bone damage in livestock. Parts of Arkansas, California, South Carolina, and Texas have soils abnormally high in fluorine content. In serious situations, diarrhea and emaciation will be exhibited by the

livestock. The effects depend upon the fluorine source and species of livestock. Exceptionally high fluoride levels can be encountered near smelters where pollution safeguards have not been installed or are ineffectively maintained. As compared with other livestock, pigs can tolerate much more fluorine (up to nearly 300 ppm of fluorine derived from rock phosphates).

Fluorine in Tea. The majority of foods found in the average diet contain 0.2−0.3 ppm or less fluorine in the food as consumed. Tea and seafoods are notable exceptions (McClure, 1949). Different values are reported for fluorine content of various teas by different investigators (Wang et al., 1949; Fabre and de Campos, 1950; de Campos, 1950; Zimmerman et al., 1957; Quentin et al., 1960; Okada and Furuya, 1969; Cook, 1970; Venkateswarlu and Sita, 1971). The fluorine content of tea depends upon the origin of the plant, the type of soil and fertilizer, the age of the leaves, and the time of harvesting (Garber, 1962).

In 1978, investigators at the University of Teheran (Iran) undertook a study to find out the fluorine content of teas consumed in Iran and to evaluate the potentiality of tea as a contributor of fluorine. Tea is an important item in the Iranian diet and drunk mostly by labourers and peasants; furthermore, diluted infused tea is used as a supplement in between breast feedings of infants. The investigators concluded that, considering the optimal intake of fluorine of 1 milligram per day suggested for protection from dental caries, the drinking of tea in Iran provides about half of this amount without considering the fluorine content of water and other sources.

Fluorine Content of Mechanically Deboned Beef and Pork. One question that has arisen from time to time in connection with mechanically deboned meat (MDM) is its possible fluoride content because some microscopic bone particles may be present in the product. Investigators Kruggel and Field, Division of Biochemistry and Division of Animal Science, University of Wyoming, made a study of this in 1977. Samples were collected from regions where high levels of fluoride occurring in the water and vegetation have been reported. Higher magnesium, iron, and fluoride contents were found in beef MDM from the western and midwestern regions of the United States when compared with the southern region. Higher iron and fluoride contents were found in beef MDM than in pork MDM. One conclusion drawn was that the consumption of fluoride from MDM and other foods combined would be far below the 20−80 milligrams or more of fluoride that must be consumed daily to produce toxicity (Food and Nutrition Board, 1974). Mottling of teeth in children has been observed at fluoride concentrations in the diet and drinking water of 2−8 ppm. A frankfurter containing 10% MDM would contain about 1.7 ppm fluoride. Since the daily fluoride intake in many areas of the United States is not sufficient to afford optimal protection against dental cavities (Food and Nutrition Board, 1974), products which contain MDM may be of value in furnishing needed fluoride and in reducing the incidence of tooth decay (Kruggel/Field, 1977).

Fluorine in Marine Sponge *Halichondria moorei*. It is well known that many marine organisms accumulate the halogens iodine, bromine, and chlorine. However, reports of fluorine accumulation have been rare. Thus the report of findings by Gregson et al. (1979) that the marine sponge *Halichondria moorei* has a fluorine content of 10% of the total dry weight is of interest. In this species, the fluorine occurs as potassium fluorosilicate, which is known to be a powerful anti-inflammatory agent. It is of interest that closely related sponge varieties of the same habitat contain little if any fluorine — and, further, that the habitat is free of fluorine except for the small amount naturally present in seawater.

FLUORITE. Fluorite is a calcium fluoride mineral CaF_2 crystallizing in the isometric system, often in superb cubic crystals. Twinned crystals are common, usually as cubic penetration twins. It is found in many diverse geological environments, from vein material associated with metallic ores, especially lead and silver, to sedimentary formations associated with celestite, gypsum, dolomite, and calcite. It is also found as a component mineral in high-temperature pneumatolytic deposits with cassiterite, topaz and tourmaline, and in pegmatites. Exceptional crystals are found in Alpine type veins on quartz crystals from Switzerland. Also occurs as massive compact to granular aggregates. Possesses perfect 4-directional cleavage planes, with uneven to splintery fracture. It is a brittle mineral with a hardness of 4 and a specific gravity of 3.180. Vitreous luster when crystallized, dull to glimmering in massive material. Colorless when pure, but shades of blue, green, yellow, brown, white, rarely rose-red and pink, are known, including intermediate color graduations of each type. Certain colored crystals appear blue by reflected light, green by transmitted light. This phenomenon may be a product of heat, ultraviolet light, pressure, or exposure to radiation, as from x-rays. Varying color zones are commonly observed in areas parallel to the crystal faces. Massive varieties may also exhibit parallel zones of varying color.

Phosphorescence is not uncommon when certain fluorites are exposed to sunlight, ultraviolet rays, or are heated. Vivid fluorescence is a common attribute of many fluorites, with blue to violet fluorescence predominant. The word fluorescence is derived from the mineral name, fluorite, owing to its strong fluorescent character.

Certain dark blue fluorite from Bavaria known as antozonite contains free fluorine and calcium, which when released either by grinding or exposure to cathode rays produce a distinctive odor, caused by the reaction of the fluorine with water.

Fluorite is a ubiquitous mineral and is so widespread in its occurrence that only the most noteworthy can be mentioned. The English localities at Cumberland, Durham, and Weardale are world famous. Exceptionally beautiful banded material of blue fibrous character from Derbyshire, known as Blue-John, has been much-used for decorative carved pieces, such as vases and other ornamental objects. Norway has produced exceptional specimens from the famous Kongsberg silver veins, as well as yttrium-rich fluorite from northern Norway associated with rare-earth minerals. Fine material has been obtained from the Transvaal in the Republic of South Africa, Tasmania, and Australia. Large quantities of fluorite are mined in Mexico at Guadalcazar and Guanajuato.

Notable United States localities include Hardin and Pope Counties in Illinois, and also adjacent Kentucky areas where it is intimately associated with calcite, barite, quartz, with minor galena and sphalerite in sedimentary rock veins. Large deep green masses yielding exceptional cleavage octahedrons were obtained from Westmoreland, New Hampshire.

Macomb, New York produced large sea-green crystallized cubes. Various sedimentary formations in Ohio have yielded fine brown crystals associated with celestite. Many occurrences are known throughout Colorado and Idaho. Optical-quality crystals have been obtained from Madoc, Ontario, Canada in association with barite and calcite; also in British Columbia near Grand Forks, and at several localities in Mexico.

Fluorite is highly valued as a flux in the manufacture of steel; also as a raw material for hydrofluoric acid. When of optical quality, the mineral is used for lens and prisms in scientific instruments.

FLUOROCARBON. A number of organic compounds analogous to hydrocarbons, in which the hydrogen atoms have been replaced by fluorine. The term is loosely used to include fluorocarbons that contain chlorine; these should properly be called chlorofluorocarbons or fluorocarbon chlorides, since it is these which are thought to deplete the ozone layer of the upper atmosphere. Fluorocarbons are chemically inert, nonflammable, and stable to heat up to 260–316°C. They are denser and more volatile than the corresponding hydrocarbons, and have low refractive indices, low dielectric constants, low solubilities, low surface tensions, and viscosities comparable to hydrocarbons. Some are compressed gases; others are liquids. These compounds were once used extensively in aerosol packages. They are used as refrigerants, solvents, blowing agents, fire extinguishers, lubricants and hydraulic fluids — as components of complete systems.

Fluorocarbon polymers include polytetrafluoroethylene, polymers of chlorotrifluoroethylene, fluorinated ethylene-propylene polymers, polyvinylidene fluoride, and hexafluoropropylene, among others. These are thermoplastic substances, resistant to chemicals and oxidation; noncombustible; with broad useful temperature range (up to 285°C); with high dielectric constant; resistant to moisture, weathering, ozone, and ultraviolet radiation. Their structure comprises a straight backbone of carbon atoms symmetrically surrounded by fluorine atoms. These materials are available as powders and dispersions for further processing, as films, sheets, tubes, rods, tapes, and fibers. They find use in high-temperature wire and cable insulation, other electrical equipment, chemical processing equipment, coatings for cooking utensils, piping, gaskets. Among the fluorocarbon polymers are a number of fluoroelastomers. These polymers are amorphous, thermally stable, noncombustible, have low glass transition temperature (−77°C), and are generally resistant to attack by solvents and chemicals.

FLUOROELASTOMER. Any elastomeric high polymer containing fluorine; they may be homopolymers or copolymers. Fluorocarbon polymers include a large group of fluoroelastomers, including a copolymer in which the molecular skeleton is a −P=N− chain containing approximately equal numbers of tri- and heptafluoroethoxy side groups. Such polymers are amorphous, thermally stable, noncombustible, generally resistant to attack by solvents and chemicals, and have low glass transition temperature (−77°C).

FLUOROMETERS. In fluorescence analysis, the amount of light emitted characteristically under suitable excitation is used as a measure of the concentration of the responsible material under observation. Thus, the method is closely related to colorimetric or spectrophotometric analysis, in which the amount of light absorbed characteristically is used to measure the concentration of the dissolved species.

The main advantage of fluorescence methods is their high sensitivity, about one part in 10^8, in many determinations both inorganic and organic. This is two or three orders of magnitude better than absorption methods, where the sensitivity is limited by the necessity of detecting a very small fractional decrease in the light transmitted by the solution.

In fluorescence, the situation is inherently more favorable. Inasmuch as zero concentration corresponds to darkness (neglecting reagent blanks), and the sensitivity depends on detecting the first faint emission of light as the concentration is increased, advantage can be taken of highly sensitive detectors, such as photomultipliers, and high-intensity ultraviolet sources for excitation. Combining these with sophisticated electronic and optical techniques has led to a remarkable achievement; under favorable conditions, it is possible to detect Rhodamine 5DGN down to the extremely low concentration of one part in 10^{12} in an instrument designed for tracing ocean currents with a fluorescent dye marker.

The use of fluorescent methods requires that the substance to be determined is fluorescent under suitable irradiation, or can be made so by a chemical reaction. Among organic substances, fluorescence is shown mainly by aromatic compounds (including such hydrocarbons as benzene, naphthalene, anthracene, and their derivatives) rather than the aliphatic series. Among the metal ions, only a few, such as uranium and thallium, show intrinsic fluorescence; but many others can be determined fluorometrically by adding a specific reagent that reacts with the metal to form a fluorescent complex. Thus, aluminum is complexed with the dye Pontachrome BBR, beryllium with morin, and zirconium with flavenol.

Various sources are used for exciting fluorescence, including proprietary lamps, mercury vapor lamps, and the xenon arc lamp. A tungsten lamp may be used for substances having a strong excitation band above 450 mμ. Both the desired excitation band and emission band may be isolated by means of interference filters. However, since the desired excitation band is usually in the ultraviolet, the tungsten lamp is not in general use, but may have specific applications. It gives a band spectrum and does not have the sharp line limitation of the mercury vapor lamps.

One proprietary lamp is similar to the ordinary fluorescent lighting tube, but contains a phosphor that emits an abundance of radiation in the 350- to 360-mμ region of the spectrum. These lamps are usually of 5 or 15 watts and operate with a simple starter and ballast. The phosphor emits visible light, which must be excluded by a filter. Mercury vapor lamps provide the only practical type of metallic arc used in fluorometry. These are designed to operate at high pressure or low pressure. The high-pressure type was made with a mercury arc at a pressure of about 8 atmospheres surrounded by a protective envelope.

If the emission is in the visible spectrum it may be estimated by visual comparison with standards. In any range of the spectrum, the intensity of the emission may be measured with a phototube, a barrier layer cell, or with a photographic plate and densitometer. By far the most common procedure is to use a phototube or an electron multiplier phototube attached to a microphotometer or a recorder.

Fluorometers are made, containing the lamps and measuring devices just discussed, along with filters and other components. Fig. 1 shows the functional elements of a fluorometer.

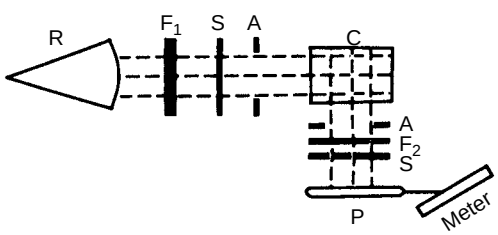

Fig. 1. Simple 90°-axis fluorometer as viewed from above: *R*, radiation source; F_1 and F_2, filters; *S*, shutters; *A*, apertures or slits; *C*, sample container.

A fluorometer constructed with two monochromators is called a *spectrofluorometer*. With the spectrofluorometer, two types of information can be obtained easily: the wavelength of best excitation and the wavelength of the strongest emission. Two curves are generally plotted on the recorder for each fluorescing material: an excitation curve and an emission curve. The *excitation spectrum* is a plot of the wavelength of the exciting source, against the intensity of the emission. The excitation wavelength producing the greatest intensity of emission would seem to be best exciting wavelength. However, this statement is true only for the particular light source and grating.

FLUOROPLASTICS. These plastic materials may be placed into two convenient categories: (1) fluorocarbon plastics, and (2) other fluoroplastics. Fluoroplastics are produced by free radical initiated polymerization or copolymerization of the monomers. Fluorocarbon plastics contain no C−H bonds; other fluoroplastics contain some C−H and/or C−Cl bonds in the basic structure.

These plastics generally are considered as tough but relatively soft materials, with high elongation. Their useful characteristics are maintained over a wide temperature range — just above absolute zero to as high as 260 °C (500 °F). They withstand chemical environments well and essentially are unaffected by all organic solvents and reactive organic and inorganic compounds. Insulation resistance is quite high; dielectric constant and dissipation factor are low; arc resistance is high; surface energy is low (good antistick performance). Fluorocarbon plastics do not support combustion in air. When exposed to fire, they resist ignition and do not promote flame spread. Other fluoroplastics are somewhat less rugged than the fluorocarbons, with somewhat less resistance to certain organic materials and extreme environmental conditions. The other fluoroplastics are regarded as stiffer and stronger, and they display less deformation under load and creep.

All fluoroplastics except polytetrafluoroethylene can be processed using melt techniques commonly applicable to thermoplastics. Processing temperatures are somewhat higher than normally used with other thermoplastics and corrosion-resistant equipment is required to resist the corrosive effects of the molten polymer.

Fluoroplastics find applications as coatings, linings, and as components of valves, fittings, gaskets, seals, and large tanks. Fluoroplastics have been used in well monitoring equipment. They also are used in wire and cable products. The family of fluoroplastics includes *polytetrafluoroethylene*, marketed under tradenames such as *Teflon, Fluon, Halon*, constituting the greatest production of fluoroplastics; *fluorinated ethylene-propylene copolymer; perfluoroalkoxy resin; ethylene-tetrafluoroethylene copolymer, polyvinylidene fluoride; polychlorotrifluoroethylene; ethylene-chlorotrifluoroethylene copolymer*, and *polyvinyl fluoride*.

FLUTTER. 1. Oscillation of definite period but unstable character set up in any part of an aircraft by a momentary disturbance, and maintained by a combination of aerodynamic, inertial, and elastic characteristics of the member itself (example, buffeting). Flutter and vibration are treated theoretically and experimentally in the field of aeroelasticity.

2. In communication practice, (a) distortion due to variations in loss resulting from the simultaneous transmission of a signal at another frequency, or (b) a similar effect due to phase distortion. (c) In recording and reproducing, the deviations in reproduced sounds from their original frequencies; these result in general from irregular motion during recording, duplication or reproduction.

FLUTTER RATE. The number of frequency-excursions in cycles per second, in a tone which is frequency-modulated by flutter. Each cyclical variation is a complete cycle of deviation, for example, from maximum-frequency to minimum-frequency and back to maximum-frequency at the rate indicated. If the overall flutter is the resultant of several components having different repetition rates, the rates and magnitudes of the individual components are of primary importance.

FLUVIAL. Derived from the Latin, meaning river, and used by geologists and physiographers to denote a river as the agent, i.e., fluvial sediments.

FLUX. 1. The rate of flow of some quantity, often used in reference to the flow of some form of energy.

2. In the field of atmospheric turbulence and boundary layers, often used as a contraction for flux density; namely, the flow of a quantity per unit area per unit time. These fluxes can be defined in two forms: dynamic and kinematic. The dynamic flux of a quantity is the flow of that quantity per unit area per unit time, where often the word dynamic is assumed if it is not explicitly stated. The advantage of a kinematic flux is that it has units that are more easily measured by a conventional meteorological instrument. The units are usually a velocity (m s^{-1}) times a temperature (K), specific humidity (kg_{water}/kg_{air}), or wind speed (m s^{-1}).

FLUX GUIDE. In induction-heating usage, the term flux guide denotes magnetic material to guide electromagnetic flux in desired paths. The guides may be used either to direct flux to preferred locations or to prevent the flux from spreading beyond definite regions.

FLUX (Luminous). The time rate of flow of luminous energy or the radiant flux evaluated by means of the standard luminosity function.

FLUX (Physics). 1. A quantity proportional to the surface integral of the normal (perpendicular) force field intensity over a given area.

$$\text{Flux} = K \int_S F_N dS$$

where F_N is the normal component of a field (e.g., gravitational, electric, magnetic), and K is the constant of proportionality between the field and the flux density (permittivity, permeability, etc).

2. A term that denotes the volume or mass of fluid or particles transferred across a given area perpendicular to the direction of flow in a given time.

There are many specific applications in physics of the term flux. For electromagnetic radiation, it signifies the energy per unit time, or the power passing through a surface. For photons or particles, flux is the number per unit time passing through a surface. In nuclear physics, flux is used by many people to mean the product nv, where n is the number of particles per unit volume and v is their mean velocity. However, the ICRU in 1962 adopted the term flux density.

FLUX REFRACTION. When a ferromagnetic body composed of two pieces of different magnetic permeability is placed in a magnetic field, or when a dielectric composed of two adjacent portions of different dielectric constant is placed in an electric field, the lines of magnetic induction in the former case, and the lines of electric displacement in the latter, if oblique to the interface, abruptly change their direction. The phenomenon is thus somewhat analogous to the refraction of light. But the law is different. Whereas in the case of light, the ratio of the sines of the angles of incidence and refraction is constant, in the case of flux refraction it is the ratio of the tangents of the angles that is constant.

For an electric current flowing across a boundary between two conductors of different electrical resistivity, there is a refraction of the lines of flow, likewise obeying the tangent law.

FLUX (Slag). A material added to the contents of a smelting furnace or a cupola for the purpose of purging the metal of impurities, and of rendering the slag more liquid. The flux most commonly used in iron and steel furnaces is limestone, which is charged in the proper proportions with the iron and fuel. The slag is a liquid mixture of ash, flux, and other impurities.

FLUX (Solder). A material which by its chemical action facilitates the soldering and brazing of metals. Such a flux applied to a metallic surface cleans it and renders it receptive to amalgamation with the solder or brazing metal. Some fluxes are rosin, for soldering tin; muriatic acid, for galvanized iron and other zinc surface; and borax for brazing.

FLY. A 2-winged insect belonging to the order *Diptera*. Also commonly applied with some qualifying word to many flying insects with membranous wings, such as May fly, dragon fly, stone fly, and caddis fly. These four examples belong to as many different orders.

Flies are probably responsible for the transmission of more infectious diseases than any other insect. True flies have only one pair of wings.

FLY-BACK. 1. The shorter of the two intervals of time that comprise a sawtooth wave.

2. The retrace motion of an electron-beam, as, for example, in a picture tube.

FLYING FISHES *(Osteichthyes).* Of the family *Exocoetidae*, the flying fishes have the ability to jump and sail through the air. As described under the entry on **Characids** (*Ostariophysi*), the South American flying hatchet fish is probably the only fish that has true flying ability, that is, an ability to apply motive power while in the air and thus to extend its jump. This is accomplished in the flying hatchet fish by movement of the pectoral fins during flight. In a lesser degree, this may also be true of the African freshwater butterfly fish. The other known flying fishes, although capable of spectacular "flights," are essentially jumpers and gliders. The *Cypselurus californicus* is the largest known of the flying fishes. It ranges from southern California down to Baja California. It has four wings in an 18-inch (46-centimeter) form. Of the flying fishes, flights up to 150 feet (45 meters) and of 3 seconds duration have been noted. Exceptional flights up to 13 seconds, with an average speed of about 35 miles (56 kilometers) per hour, also have been recorded. A well known 2-wing form is the 10-inch (25-centimeter) *Exocoetus volitans*, found worldwide in tropical waters. See also **Gurnards**.

FLYWHEEL. Prior to the serious concerns over future energy sources, the flywheel was normally envisioned in its conventional use as a way to steady the speed of rotating equipment. The ability of a flywheel to provide remarkable assistance to speed control of a rotating machine lies in its capacity to absorb and release energy with small variations in speed. This quality of a flywheel can make it useful as an energy-storage medium in certain kinds of energy systems.

Since the kinetic energy contained by a rotating flywheel is $\frac{1}{2}I\omega^2$, I being the moment of inertia of the mass about the center of rotation, ω being the angular velocity in radian units, energy will be absorbed when ω changes slightly only upon the condition that I be a large quantity. Consequently, flywheels are characterized by large moments of inertia. Mass alone is no criterion for the "flywheel effect," however, because the moment of inertia is involved as well as the disposition of the mass. Thus, the shape of the body becomes important. In practice, not only are flywheels massive, but also the mass is placed *as far as practical from the center of rotation*, as provided, for example, by a heavy rim. The flywheel effect, then, is obtained whenever a large mass having a large moment of inertia about its center of rotation is constructed. The large moment of inertia about the center of rotation steadies the rotational motion in the face of uneven power impulses through the process of absorbing or releasing kinetic energy by slight changes of angular rotation.

In the hydraulic turbine field, the flywheel effect has a very special meaning. The magnitude of the flywheel effect of a hydraulic turbine is determined by the weight of its rotating element, multiplied by the square of the radius of gyration of the same.

Energy Storage. A major problem in attempts to use so-called unconventional sources of energy is the severe limitations imposed by the need to store energy from a cyclical source (direct heat radiation from the sun, mechanical energy from the sun in the form of wind, etc.). Central electric power-generating stations, which are now tied together by way of vast interconnecting networks in many countries, and which also have oversize units to handle peak loads, are to be contrasted with smaller wind-generating facilities which, for example, located in remote regions or developing countries, cannot utilize a grid for the transfer of energy. Thus, the possible use of flywheel technology is being considered along with batteries and other less conventional energy storage approaches.

The theoretical limit placed upon the amount of kinetic energy a flywheel can store is the strength or usable stress of the wheel. In other words, what is the safe rotating speed beyond which there is a risk of the wheel disintegrating (flying apart)? As observed by Millner, considering the present state of the art, "The cost of storage, say per kilowatt-hour, is proportional to the strength-to-weight ratio of the material and its cost per pound. High strength per unit weight is important only in weight-limited applications, such as vehicles; for low-cost stationary systems, expensive materials such as titanium, steel, and aluminum, from which flywheel rotors traditionally have been made, are precluded. Rotors made of these metals cost over $200 per kilowatt-hour stored."

Researchers at the M.I.T. Lincoln Laboratory indicate that, considering a material capable of storing 10 to 20 watt-hours per pound (22 to 44 watt-hours per kilogram) would have to weigh from 1 to 2 tons (0.9 to 1.8 metric tons). It is envisioned that such a rotor would be from 3 to 4 feet (0.9 to 1.2 meters) in diameter and about 3 feet (1 meter) in thickness. This could be appropriate for a solar- or wind-powered residence, for example, that consumes some 25 kilowatt-hours of energy per day and needs 1 day of storage. For a large, commercial installation, such as a school, apartment building, or shopping center, the rotor would have to be about ten times heavier and perhaps have a diameter of about 6 feet (1.8 meters). For comparison, a utility substation with the requirement to store ten times the energy of a commercial situation would have to weigh some 20 tons (18 metric tons) and perhaps be 12 feet (3.6 meters) in diameter. In terms of safety, such wheels could be installed in pits in the ground, which would absorb the energetic impact of a disintegrating rotor.

Some materials (*anisotropic*) have their strength principally in one direction and experiments have shown that they can outperform solid steel, for example, as material for a rotor. Examples of anisotropic materials that may be appropriate for flywheels include high-quality steel wire and coated glass fibers. New materials along these lines are being developed. A "bare-filament" flywheel made from such materials has been likened to a spool of yarn. The fragmentation patterns of these structures are also less dangerous, as they have a tendency to disintegrate more slowly (unwinding, so to speak).

To take energy out of storage from a rotating flywheel, conversion to electricity, using the rotor as part of an electric generator, is the immediately obvious means. Conventional motor-generator design requires either brushes or slip rings to transmit current between stator and rotor. Investigators have been working on a brushless motor-generator contained inside a vacuum chamber. Numerous configurations have potential. One of these is a special circuit called a *cycloconverter*. As described, this device is made up of a group of electronic switches that are placed between the flywheel output phases and the load. In a programmable way of manipulating the switches in accordance with a timing sequence, high frequency output of a flywheel's motor-generator can be made to approximately duplicate a desired output voltage.

Another important aspect that must be studied and perfected, in instances where a flywheel is expected to store energy for comparatively long periods (days or weeks), is the need for a minimum of drag (as from air) on the rotor and very minimal friction in the bearings.

Bearing specifications for the task are quite demanding. Considering the residential-size flywheel previously described, the bearings must support a ton or two of mass and revolve at from 10,000 to 15,000 revolutions per minute. The bearings also must be able to tolerate some conditions of imbalance. Researchers have not found ball, roller, and needle bearings very successful under these conditions. Magnetic bearings, which remove physical contact between rotor and stator and which are used successfully in the aerospace field, appear to have considerable potential for energy-storing flywheels. Researchers have indicated that about ten pounds (4.5 kilograms) of magnets can support the weight of the rotor. A servosystem can be used to stabilize the rotor position. Particularly when installed in an evacuated system, the life expectancy of such bearings is expressed in terms of several years.

FOAM. Foam is a nonequilibrium dispersion of gas bubbles in a relatively smaller volume of liquid. An essential ingredient in a liquid-based foam is surface-active molecules. These reside at the interfaces and

are responsible for both the tendency of a liquid to foam and the stability of the resulting dispersion of bubbles. For example, it is common experience that a relatively stable foam can be made by bubbling gas through soapy water, but not through pure water. Important uses for custom-designed foams vary widely from familiar examples of detergents, cosmetics, and foods, to fire extinguishing, oil recovery, and a host of physical and chemical separation techniques. Unwanted generation of foam, on the other hand, is a common problem affecting the efficiency and speed of a vast number of industrial processes involving the mixing or agitation of multicomponent liquids. In all cases, control of foam rheology and stability is desired. These physical properties, in turn, are determined by both the physical chemistry of their liquid–vapor interfaces and by the structure formed from the collection of gas bubbles.

Observed from a distance, foam made from a clear liquid appears homogeneous and white. When observed more closely, however, the intricate structure formed by the close packing of distinct gas bubbles becomes apparent. In practice, the average bubble size and shape in a foam can be altered for a given liquid according to the production method, the surface-active ingredients, and other chemical additives such as viscosity modifiers or polymeric stabilizers.

The nonequilibrium nature of foams is revealed by the time evolution of their structures. In addition to drainage, two other mechanisms by which foams evolve are by direct coalescence of neighboring bubbles via film rupture and by the diffusion of gas molecules through the liquid from small bubble to large bubbles. No matter which of these three processes dominates for a given foam, the liquid and vapor portions invariably consolidate and separate with time; in equilibrium there is no foam, only one region of liquid and one of vapor. The physical chemistry of the interfaces and the foam structure primarily determine the relative rates of the three aging mechanisms.

Foams that are relatively stable on experimentally accessible time scales can be considered a form of matter but defy classification as either solid, liquid, or vapor. They are solid-like in being able to support shear elastically; they are liquid-like in being able to flow and deform into arbitrary shapes; and they are vapor-like in being highly compressible. The rheology of foams is thus both complex and unique, and makes possible a variety of important applications. Many features of foam rheology can be understood in terms of its microscopic structure and its response to macroscopically imposed forces.

Physical Chemistry of Interfaces

The chemical composition, physical structure, and key physical properties of a foam, namely its stability and rheology, are all closely interrelated. Since there is a large interfacial area of contact between liquid and vapor inside a foam, the physical chemistry of liquid — vapor interfaces and their modification by surface-active molecules plays a primary role underlying these interrelationships.

For aqueous solutions, the chemical constituents most commonly responsible for foaming are surfactants, i.e., surface-active agents. Such molecules find wide use in other settings, and are distinguished by having both hydrophilic and hydrophobic regions.

Physical Properties of Foam

Based on the underlying physical chemistry of surfactants at interfaces, important features of foam structure, stability, rheology, and their interrelationships can be considered as ultimately originating in the molecular composition of the base liquid.

Foam structure is characterized by the “wetness” of the system. Foams with arbitrarily large liquid to gas ratios can be generated by excessive agitation or by intentionally bubbling gas through a fluid. If the liquid content is sufficiently great, the foam consists of well-separated spherical bubbles that rapidly rise upwards displacing the heavier liquid. Such a system is usually called a froth, or bubbly liquid, rather than a foam.

A dry foam, by contrast, is one with so little liquid that the bubbles are severely distorted into approximately polyhedral shapes. Typically this occurs for foams with less than 1% liquid by volume.

A complete characterization of the structure of a foam requires a characterization of the structure of the bubbles that comprise the foam.

Control of foam stability is important in all applications, whether degradation of a custom foam is to be minimized or whether excessive foaming is to be prevented. In all cases, the time evolution of the foam structure provides a natural means of quantifying foam stability. There are three basic mechanisms whereby the structure may change: by the gravitational segregation of liquid and bubbles, by the coalescence of neighboring bubbles via film rupture, and by the diffusion of gas across the liquid between neighboring bubbles.

Any means of characterizing foam structure can be used to study foam evolution, provided that the measurement can be made noninvasively and sufficiently rapidly. For defoaming applications, this is often a more important measure of stability than the foam structure.

The rheology of foam is striking; it simultaneously shares the hallmark rheological properties of solids, liquids, and gases, and their mechanical response to external forces can be very complex.

To determine rheological parameters such as the yield stress and effective viscosity of a foam, commercial rheometers are available; rotational and continuous-flow-tube viscometry are most commonly employed. See also **Rheology**. However, obtaining reproducible results independent of the sample geometry is a difficult goal which arguably has not been achieved in most of the experiments reported in the scientific literature.

Production

Several techniques are available for the generation of special-purpose foam with the desired properties. The simplest method is to disperse compressed gas directly into an aqueous surfactant solution by means of a glass frit. A variation of this method that allows for control of liquid content is to simultaneously pump gas and surfactant solution through a bead pack or steel wool, for example, at fixed rates. In the same spirit, another solution, which can be used for laboratory purposes, consists of pushing a pressurized surfactant solution through a single pinhole, and to add any desired gas flow rate just after that pinhole. Large amount of foams, at any liquid fractions, are then produced by the subsequent turbulent mixing of these fluids inside a final tube of confinement. Less reproducible mechanical means of foam generation include brute force shaking and blending. For highly reproducible foams composed of small bubbles, such as shaving creams, the aerosol technique is especially suitable. See also **Aerosols**. Hydrocarbons or chlorofluorocarbons are liquefied at high pressure and then emulsified with the surfactant solution. When released to atmospheric pressure, the propellant droplets evaporate into tiny gas bubbles which aggregate into a foam.

Applications

Foams have a wide variety of applications that exploit their different physical properties. The low density, or high volume fraction of gas, enable foams to float on top of other fluids and to fill large volumes with relatively little fluid material. These features are of particular importance in their use for fire fighting. The very high internal surface area of foams makes them useful in many separation processes. The unique rheology of foams also results in a wide variety of uses, as a foam can behave as a solid, while still being able to flow once its yield stress is exceeded.

Foams are also widely encountered in circumstances where their presence is detrimental. Foams are common to many processes that entail agitation of fluids or bubbling of air through fluids. The presence of any type of surface-active ingredient, even in minute quantities, enhances the formation of foams in the processing. The presence of the foams increases the volume of the fluids and makes them more difficult to process and transport. Moreover, foams can have strong detrimental environmental effects. Thus, just as the production and stabilization of foams is important in some industrial processes, so the elimination of foams is crucial in many others. As a result, a wide variety of defoaming agents have been developed to eliminate or reduce the formation of foams. See also **Defoaming Agents**.

Foams are widely used in firefighting applications. They are particularly useful in extinguishing flammable liquids, eg, gasoline. Whereas water simply agitates the gasoline, further spreading the fire, and then sinks to the bottom of the burning fluid, a foam is less dense than the burning liquid, and remains suspended on its surface. The collapsing bubbles cool the fluid near the surface, and reduce the amount of oxygen available to the flame, ultimately extinguishing it. A foam is also a more efficient use of the firefighting liquid, typically water, enabling it to be spread over a much larger area.

Foams are common to a wide variety of food products. Whipped cream and meringue are essentially foams, and ice cream is comprised of a large amount of foam. These foams are stabilized by proteins; the two most important are egg white and milk proteins. For food products, it is desirable not only to achieve good foaming properties, but also to form stable foams.

The ease with which foams are formed depends on the capacity of the proteins to rapidly adsorb onto the interface. One of the best food-foaming agents is egg white or egg albumen. It consists of a mixture of different proteins, each serving a particular function.

Another important digestible foam is that on the top of a glass of freshly poured beer. Although not as long lasting, it is nevertheless considered an important aesthetic quality of the beverage, and is thus the subject of considerable research.

Foams have important uses in separations, both physical and chemical. These processes take advantage of several different properties of foams. The buoyancy and mechanical rigidity of foam is exploited to physically separate some materials. The large volume of vapor in a foam can be exploited to filter gases. The large surface area of a foam can also be exploited in the separation of chemicals with different surface activities.

Froth flotation is a significant use of foam for physical separations. It is used to separate the more precious minerals from the waste rock extracted from mines. This method relies on the different wetting properties typical for the different extracts.

Foams find wide use in oil recovery, from the initial drilling of the bore holes, through the first recovery stage, and, increasingly, all the way to tertiary or enhanced oil recovery. Again, this application exploits the unique features of foams, primarily the large interfacial area and the distinctive rheological properties of flowing foams.

In the drilling of oil wells, foam is sometimes used as the drilling fluid. See also **Foamed Plastics**.

Detergents. Foams are often associated with detergents, but they are generally not essential. Instead, foaminess is often a desirable trait more for its effect on the consumer than its function. In fact, excessive foaming can be detrimental to the cleaning if the volume of the foam is too high. One exception is the case where the cleansing action must be restricted to some particular region, and where excessive amounts of water must be avoided.

Foams are often encountered in the production of textiles, which involves extensive interactions between the fibers, which have a large surface area, and a variety of aqueous treatments. In most cases, these foams are detrimental to the processing and fabrication of the textiles and measures are taken to reduce the foaming. These include modifications of the mechanical fabrication techniques, addition of foam inhibitors, and the use of low foaming surfactants in the processing. However, in other instances, foams can be used advantageously in textile processing, primarily for the application of screen printing, coatings, backings, and certain types of dyes. Foams can also be used to clean textiles as the foam helps wet between the fibers thereby more effectively spreading the detergent.

Besides the esthetic appeal of foams, they have two properties that are exploited for cosmetic purposes. The first is their ability to retain different substances and distribute them as required, while using a relatively small quantity of fluid. An example of this application is the lather formed by some shampoos, which effectively spreads the detergent by wetting the surfaces of the hair, while avoiding excessive liquid that would otherwise fall off. The second application is to spread a moisturizer or lubricant, while still providing enough resiliency to hold the fluid in place. A prime example of this is shaving cream, which provides both moisturization and lubrication for shaving. See also **Detergents**.

Safety, Health, and Environment

Foams play important roles in environmental issues, both beneficial and detrimental.

Many water systems have a natural tendency to produce foam upon agitation. The presence of pollutants exacerbates this problem. This was particularly severe when detergents contained surfactants that were resistant to biodegradation. Then, water near industrial sites or sewage disposal plants could be covered with a blanket of stable, standing foam. However, surfactant use has switched to biodegradable molecules, which has greatly reduced the incidence of these problems.

The treatment of wastewater, either from sewage or from industrial processes, typically entails a preliminary filtration to remove the large volumes of solids, and then a slower settling to remove the sand and gravel. See also **Wastes and Pollution**; and **Water Pollution**. The water is then treated by an activated sludge process to remove the remaining dissolved solids and organic colloidal particles. Activated sludge is a biomass that assists in the degradation of the organic waste in the water. The process entails a mixing and aeration of the wastewater with the activated sludge, which can lead to problems of foaming. The foams produced can be quite stable, resulting in additional problems for waste disposal. The foams produced in this process differ from those normally encountered in that the foam producing and stabilizing agents are microbial, primarily including Nocardia, Microthrix parvicella, and Rhodococcus. These foams are more difficult to treat with defoaming agents. Moreover, it is very difficult to predict the degree of foamability of the waste being treated (108). In other, more specialized wastewater treatments, these problems do not arise, and defoaming agents can be used effectively. For example, the wastewater remaining from the pulp used in the production of paper contains dissolved soaps from fatty acids and abietes, which can lead to foam problems. These can be controlled with mixtures of organic solvents and nonionic surfactants or with gaseous sulfur dioxide.

There still is no completely satisfactory propellant for use in the aerosol method of foam production. Chlorofluorocarbons, still widely used, are harmful to atmospheric ozone and low molecular weight hydrocarbons, now popular, e.g., in producing shaving cream, are explosive and promote the greenhouse effect. See also **Fluorine**.

FOAMED PLASTICS. Foamed polymers, otherwise known as cellular polymers or polymeric foams, or expanded plastics have been important to human life since primitive people began to use wood, a cellular form of the polymer cellulose. See also **Cellulose**. The high strength-to-weight ratio of wood, good insulating properties of cork and balsa, and cushioning properties of cork and straw have contributed both to the incentive to develop and to the background knowledge necessary for development of the broad range of cellular synthetic polymers in use.

The first cellular synthetic plastic was an unwanted cellular phenol–formaldehyde resin produced by early workers in this field. The elimination of cell formation in these resins, as given by Baekeland in his 1909 heat and pressure patent (U.S. Pat. 942,699 (Dec. 7, 1909), L. H. Baekeland), is generally considered the birth of the plastics industry. The first commercial cellular polymer was sponge rubber, introduced between 1910 and 1920 [E. W. Madge]. Cellular polymers have been commercially accepted in a wide variety of applications since the 1940s.

Classification

A cellular plastic has been defined as a plastic the apparent density of which is decreased substantially by the presence of numerous cells disposed throughout its mass. In this article the terms cellular plastic, foamed plastic, expanded plastic, and plastic foam are used interchangeably to denote all two-phase gas-solid systems in which the solid is continuous and composed of a synthetic polymer or rubber.

The gas phase in a cellular polymer is distributed in voids, pores, or pockets called cells. If these cells are interconnected in such a manner that gas can pass from one to another, the material is termed open-celled. If

the cells are discrete and the gas phase of each is independent of that of the other cells, the material is termed closed-celled.

Foamed plastics can be prepared by a variety of methods. The most important process, by far, consists of expanding a fluid polymer phase to a low density cellular state and then preserving this state. This is the foaming or expanding process. Other methods of producing the cellular state include leaching out solid or liquid materials that have been dispersed in a polymer, sintering small particles, and dispersing small cellular particles in a polymer. The latter processes are relatively straightforward processing techniques but are of minor importance.

The expansion process consists of three steps: creating small discontinuities or cells in a fluid or plastic phase; causing these cells to grow to a desired volume; and stabilizing this cellular structure by physical or chemical means.

Manufacturing Processes

Cellular plastics and polymers have been prepared by a wide variety of processes involving many methods of cell initiation, growth, and stabilization. The most convenient method of classifying these methods appears to be based on the cell growth and stabilization processes. The growth of the cell depends on the pressure difference between the inside of the cell and the surrounding medium. Such pressure differences may be generated by lowering the external pressure (decompression) or by increasing the internal pressure in the cells (pressure generation). Other methods of generating the cellular structure are by dispersing gas (or solid) in the fluid state and stabilizing this cellular state, or by sintering polymer particles in a structure that contains a gas phase.

Foamable compositions in which the pressure within the cells is increased relative to that of the surroundings have generally been called expandable formulations. Both chemical and physical processes are used to stabilize plastic foams from expandable formulations. There is no single name for the group of cellular plastics produced by the decompression processes. The various operations used to make cellular plastics by this principle are extrusion, injection molding, and compression molding. Either physical or chemical methods may be used to stabilize products of the decompression process.

Expandable Formulations. Cellular polystyrene [CAS: 9003-53-6], the outstanding example; poly(vinyl chloride) [CAS: 9002-86-2]; copolymers of styrene and acrylonitrile (SAN copolymers [CAS: 9003-54-7]); and polyethylene [CAS: 9002-88-4] can be manufactured by the physical stabilization process.

There are two types of expandable polystyrene processes: expandable polystyrene for molded articles and expandable polystyrene for loose-fill packing materials.

Cellular poly(vinyl chloride) can be produced from several expandable formulations as well as by decompression techniques. Rigid or flexible products can be made depending on the amount and type of plasticizer used.

Because polyethylene has a sharp melting point and its viscosity decreases rapidly over a narrow temperature range above the melting point, it is difficult to produce a low density polyethylene foam with nitrogen or chemical blowing agents because the foam collapses before it can be stabilized. This problem can be eliminated by cross-linking the resin before it is foamed, which slows the viscosity decrease above the melting point and allows the foam to be cooled without collapse of cell structure.

Chemical stabilization processes are more versatile and thus have been used successfully for more materials than the physical stabilization process. Chemical stabilization is more adaptable for condensation polymers than for vinyl polymers because of the fast yet controllable curing reactions and the absence of atmospheric inhibition. Foamed plastics produced by these processes include polyurethane foams, polyisocyanurates, and polyphenols.

It is possible to generate a wide variety of polyurethane foams for such diverse uses as wood replacement in decorative cabinetwork or all-foam mattresses; to insulate portable coolers or for ultrasoft furniture cushions; as a sprayed-on insulating foam for pipes; or molded seat cushions for cars. See also **Urethane Polymers**.

The isocyanurate ring formed by the trimerization of isocyanates is known to possess high thermal and flammability resistance as well as low smoke generation during burning. Aluminum foil-faced sheets of modified isocyanurate-based foams are now widely used as an insulation material. See also **Isocyanates, Organic**.

Another increasingly important example of the chemical stabilization process is the production of phenolic foams by cross-linking polyphenols (resoles and novolacs). See also **Phenolic Resins**. The principal features of phenolic foams are low flammability, solvent resistance, and excellent dimensional stability over a wide temperature range, so that they are good thermal insulating materials.

Dispersion Processes. In several techniques for producing cellular polymers, the gas cells are produced by dispersion of a gas or liquid in the polymer phase followed, when necessary, by stabilization of the dispersion and subsequent treatment of the stabilized dispersion. In frothing techniques a quantity of gas is mechanically dispersed in the fluid polymer phase and stabilized. In another method, solid particles are dispersed in a fluid polymer phase, the dispersion stabilized, and then the solid phase dissolved or leached, leaving the cellular polymer. Still another method relies on dispersing an already cellular solid phase in a fluid polymer and stabilizing this dispersion. This results directly in cellular polymers called syntactic foams.

The properties of a foamed plastic can be related to several variables of composition and geometry often referred to as structural variables. These variables include polymer composition, density, cell structure (i.e., cell size, cell geometry, and the fraction of open cells), and gas composition.

Rigid Cellular Polymers. A separate class of high density, rigid cellular polymers has grown continually since the 1970s to become significant commercially. These are the structural foams with a density $>300\ kg/m^3$. They are treated here as a separate category of rigid foams.

Compressive strength and modulus are widely used as general criteria to characterize the mechanical properties of rigid plastic foams. Rigid cellular polymers generally do not exhibit a definite yield point when compressed but instead show an increased deviation from Hooke's law as the compressive load is increased. Structural variables that affect the compressive strength and modulus of a rigid plastic foam are, in order of decreasing importance: plastic-phase composition, density, cell structure, and plastic state.

The creep characteristic of plastic foams must be considered when they are used in structural applications. Data on the deformation of polystyrene foam under various static loads have been compiled. There are two types of creep in this material: short-term and long-term. The minimum load required to cause long-term creep in molded polystyrene foam varies with density ranging from 50 kPa (7.3 psi) for foam density 16 kg/m^3 (1 lb/ft^3) to 455 kPa (66 psi) at foam density 160 kg/m^3 (10 lb/ft^3).

The successful application of time–temperature superposition for polystyrene foam is particularly significant in that it allows prediction of long-term behavior from short-term measurements. This is of interest in building and construction applications.

Structural Foams. Structural foams are usually produced as fabricated articles in injection molding or extrusion processes. The optimum product and process match differs for each fabricated article, so there are no standard commercial products for one to characterize. Rather there are a number of foams with varying properties. The most important structural variables are again polymer composition, density, and cell size and shape.

Flexible Cellular Polymers. The application of flexible foams has been predominantly in comfort cushioning, packaging, and wearing apparel, resulting in emphasis on a different set of mechanical properties than for rigid foams. The compressive nature of flexible foams (both static and dynamic) is their most significant mechanical property for most uses. Other important properties are tensile strength and elongation, tear strength, and compression set. These properties can be related to the same set of structural variables as those for rigid foams.

Other Properties

The thermal, electrical, acoustical, and chemical properties of all cellular polymers are of such a similar nature that the discussions of these properties are not separated into rigid and flexible groups.

Thermal Properties. More information is available relating thermal conductivity to structural variables of cellular polymers than for any other property.

The thermal conductivity of most materials decreases with temperature and can change upon aging under ambient conditions if the gas composition is influenced by such aging. Thermal conductivity of foamed plastics has been shown to vary with thickness. This has been attributed to the boundary effects of the radiant contribution to heat-transfer.

The specific heat of a cellular polymer is simply the sum of the specific heats of each of its components.

The coefficients of linear thermal expansion of polymers are higher than those for most rigid materials at ambient temperatures because of the supercooled-liquid nature of the polymeric state, and this applies to the cellular state as well. When cellular polymers are used as components of large structures, the coefficient of thermal expansion must be considered carefully because of its magnitude compared with those of most nonpolymeric structural materials.

Because the cellular materials, like their parent polymers, gradually decrease in modulus as the temperature rises rather than undergoing a sharp change in properties, it is difficult to precisely define the maximum service temperature of cellular polymers. The upper temperature limit of use for most cellular polymers is governed predominantly by the plastic phase.

Work aimed at developing tests to evaluate the performance of plastic foams in actual fire situations continues. All plastic foams are combustible, some burning more readily than others when exposed to fire. Some additives, when added in small quantities to the polymer, markedly improve the behavior of the foam in the presence of small fire sources.

Plastic foams are advantageous compared to other thermal insulations in several applications where they are exposed to moisture pickup, particularly when subjected to a combination of thermal and moisture gradients.

Electrical Properties. Cellular polymers have two important electrical applications. One takes advantage of the combination of inherent toughness and moisture resistance of polymers along with the decreased dielectric constant and dissipation factor of the foamed state to use cellular polymers as electrical-wire insulation. The other combines the low dissipation factor and the rigidity of plastic foams in the construction of radar domes. Polyurethane foams have been used as high voltage electrical insulation.

Environmental Aging. All cellular polymers are subject to a deterioration of properties under the combined effects of light or heat and oxygen. The response of cellular materials to the action of light and oxygen is governed almost entirely by the composition and state of the polymer phase.

Comfort cushioning is the largest single application of cellular polymers; flexible foams are the principal contributors to this field. However, the rapid growth rate of structural, packaging, and insulation applications has brought their volume over that of flexible foams during the past few years.

Commercial Products

Flexible Polyurethane. Carpet underlayment is a substantial market. Most furniture for flexible polyurethane cushioning is made from blocks of slab-produced polyurethane foam in the density range of 16 to 29 kg/m^3 (1.0–1.8 lbs/ft^3). The furniture market for polyurethane foams tends to reflect the current economic trends.

For passenger car seating about 90% is made by the molded foam process. The transportation market has experienced a decline since 1979 due to decreased automotive production and also because U.S. cars have been downsized, resulting in the use of less polyurethane foam per ca.

Consumption of polyurethane foam in bedding reached a maximum in 1978 and has since declined. Textile uses, however, are a relatively stable area and consist of the lamination of polyester foams to textile products, usually by flame lamination or electronic heat sealing techniques.

Rigid Polyurethane. The principal use for rigid polyurethane foams is for insulation in various forms utilized by a variety of industries. Packaging constitutes another significant use and is often a foam-in-place operation to protect industrial equipment such as pumps or motors.

Polystyrene. There are five basic types of polystyrene foams produced in a wide range of densities and employed in a wide variety of applications: *(1)* extruded polystyrene board; *(2)* extruded polystyrene sheet; *(3)* expanded bead molding; *(4)* injection molded structural foam; and *(5)* expanded polystyrene loose-fill packaging.

Expanded polystyrene bead molding products account for the largest portion of the drinking cup market and are used in fabricating a variety of other products including packaging materials, insulation board, and ice chests. The insulation value, the moisture resistance, and physical properties are inferior to extruded boardstock, but the material cost is much less.

Expanded polystyrene loose-fill packaging materials are used as dunnage or space filling materials for cushion packaging. They have good shock absorbency, excellent resiliency, and are odorless.

In residential sheathing insulation, fiberboard is still the most widely used product, although the use of extruded and molded polystyrene foam and of foilfaced isocyanurate foam is increasing depending on the cost, the amount of insulation required, and compatibility of insulation with other construction systems. In cavity-wall insulation, mineral wool, polyurethane, urea–formaldehyde, and fiber glass are widely used, although fiber glass batt is the most economical insulation for stud-wall construction. In mobile and modular homes, cellular plastics are used widely because of their light weight and more efficient insulation value.

Primary application of polystyrene foam sheet is as a packaging material in items such as disposable dishes and food containers, trays for meat, poultry and produce products, and egg cartons.

Injection molded structural polystyrene foam is used widely for high density items such as picture frames, furniture, appliances, housewares, utensils, toys, pipes, and fittings. Most of these products are produced by injection molding or profile extrusion methods from impact modified polystyrene. Almost all high density foam products are produced with a chemical blowing agent that releases either nitrogen or carbon dioxide, typically sodium bicarbonate or azodicarbonamides. Medium density products can be produced with either a physical or chemical blowing agent, or a combination of both.

Poly(vinyl chloride). Cellular poly(vinyl chloride) (PVC) foam is available in both flexible and rigid foams. Furniture and motor vehicle upholstery is the largest market for flexible vinyl foams. Because of better aesthetics (leather-like plastics), comfort, and favorable pricing, they are expected to show good growth in upholstery, carpet backing, resilient floor coverings, outerwear, footwear, luggage, and handbags. The only application for flexible vinyl foams in protective packaging applications is for stretch pallet wraps. These wraps are produced by extrusion.

Rigid vinyl foams in construction markets have grown substantially due to improved techniques to manufacture articles with controlled densities and smooth outer surfaces. Wood molding substitute for door frames and other wood products is an area that has grown. Rigid vinyl foams are also used in the manufacture of pipes and wires as resin extenders and in sidings and windows as the replacement of wood or wood substitutes.

Polyethylene. There are three basic types of polyethylene foams of importance: *(1)* extruded foams from low density polyethylene (LDPE); *(2)* foam products from high density polyethylene (HDPE); and *(3)* cross-linked polyethylene foams. Other polyolefin foams have an insignificant volume as compared to polyethylene foams and most of their uses are as resin extenders.

Extruded low density foam produced from LDPE is a tough, flexible, and resilient closed-celled foam used in a wide variety of applications such as cushion packaging and safety components.

HDPE foam is primarily used as a high density rigid product.

Cross-linked polyethylene foams have finer texture and a softer, more resilient feel than extruded low density polyethylene foams and are used in comfort cushioning and cushion packaging applications.

Health and Safety

Plastic foams are organic in nature and, therefore, are combustible. They vary in their response to small sources of ignition because of composition and/or additives. All plastic foams should be handled, transported, and used according to manufacturers' recommendations as well as applicable local and national codes and regulations.

Virtually all plastic foams are blown with inert gases (CO_2, N_2, H_2O). Among these blowing agents, hydrocarbons and some of the HCFs and HFCs are flammable and pose a fire hazard in handing at the manufacturing plants.

Certain organic compounds are found to be smog generating substances because of their high photochemical reactivity at ambient conditions. Since fully or partially halogenated hydrocarbons are considered to have low reactivity in the lower atmosphere (troposphere), substitution of photochemically reactive compounds for the current blowing agents may reduce ozone depletion in the stratosphere, but has adverse impact on the indoor ambient air quality. Therefore, ozone/oxidant interaction with the total environment needs to be considered in developing environmentally acceptable alternative blowing agents.

The presence of additives or unreacted monomers in certain plastic foams can limit their use where food or human contact is anticipated. Heavy metals can also be found in various additives. The manufacturers' recommendations or existing regulations again should be followed for such applications.

FOCAL COLLIMATOR. A type of collimator consisting of an objective lens at one end of a tube, and a pair of cross hairs placed accurately in its focal plane at the other end.

FOCAL LENGTH. The distance from the object or image principal point to its corresponding focal point is the object or image focal length.

FOCAL POINT. The object and image points in an optical system conjugate to infinity.

FOCOMETER. An instrument for measuring the focal length of an optical system.

FOCUSING. The process of controlling the convergence and divergence of a beam of particles or radiations.

FOCUSING COLLISION. The focusing phenomenon when a bundle of energy passes down a row of atoms following on the collision of an energetic particle with a lattice atom in a crystal. This phenomenon is important in estimates of energy losses when considering radiation damage in crystals.

FOEHN CLOUD. See **Clouds and Cloud Formation**.

FOEHN (or FÖHN). See **Winds and Air Movement**.

FOEHN WALL. See **Clouds and Cloud Formation**.

FOG AND FOG CLEARING. Fog is a hydrometeor, a visible aggregate of minute droplets or ice crystals suspended in the atmosphere near the earth's surface, the result of condensation and consequent formation of water droplets or ice crystals in the atmosphere. According to international definition, fog reduces visibility to below 1 kilometer (0.62 mile). Fog differs from cloud only in that the base of fog is at the earth's surface while clouds are above the surface. When composed of ice crystals, it is termed ice fog. Visibility reduction in fog depends on concentration of cloud condensation nuclei and the resulting distribution of droplet sizes. Patchy fog may also occur, particularly where air of different temperature and moisture content is interacting, which sometimes make these definitions difficult to apply in practice. Fogs of all types originate when the temperature and dewpoint of the air become identical (or nearly so). This may occur through cooling of the air to a little beyond its dewpoint (producing advection fog, radiation fog or upslope fog), or by adding moisture and thereby elevating the dewpoint (producing steam fog or frontal fog). Fog seldom forms when the dewpoint spread is greater than $4\,^{\circ}$F ($-16\,^{\circ}$C). In United States weather observing practice, fog that hides less than 0.6 of the sky is called *ground fog* . If fog is so shallow that it is not an obstruction to vision at a height of 6 ft above the surface, it is called simply shallow fog. In aviation weather observations fog is encoded F, and ground fog GF. Fog is easily distinguished from haze by its higher relative humidity (near 100 %, having physiologically appreciable dampness) and gray color. Haze does not contain activated droplets larger than the critical size according to Köhler theory. Mist may be considered an intermediate between fog and haze; its particles are smaller (a few μ m maximum) in size, it has lower relative humidity than fog, and does not obstruct visibility to the same extent. There is no distinct line, however, between any of these categories. Near industrial areas, fog is often mixed with smoke, and this combination has been known as smog. However, fog droplets are usually absent in photochemical smog, which only contains unactivated haze droplets. See also **Pollution (Air)**.

Temperature Structure in Fog. All fogs, except steam fog, are capped by a layer of air whose temperature is greater than the temperature of the fog. This inversion of temperature sometimes reaches magnitudes of $50\,^{\circ}$F ($\sim 28\,^{\circ}$C). Inversions of temperature thermally isolate the foggy air from the warmer, usually much drier and clear air above. Fog usually will not clear unless the inversion is destroyed or swept away. Over warm ocean waters and in the subtropics and tropics, inversions of temperature near the earth surface are rare. For this reason, fogs are also uncommon over that zone of the earth (between 30°N and 30°S).

Supercooled fog is fog having a temperature less than $0\,^{\circ}$C ($32\,^{\circ}$F). It consists of small droplets at temperatures less than freezing which can exist as liquid down to approximately $-40\,^{\circ}$C ($-40\,^{\circ}$F). Below this temperature, ice crystals tend to form automatically and the fog changes to ice fog.

Fog Seeding for Thinning and Dispersion. Supercooled fog, when "seeded" with dry ice (solid carbon dioxide) particles or with vaporizing liquid propane gas, will change to ice crystals, which fall to the ground and clear the fog. Dry ice particles falling through super-cooled fog leave a trail of very small ice crystals which, become nuclei upon which the water vapor of the supercooled droplets is deposited. The ice nuclei grow and the droplets disappear. Many of the ice crystal particles fall to the ground, thus clearing the fog. Vaporizing liquid propane causes excessive cooling which, in turn, stimulates the creation and growth of ice nuclei. These ice particles act in the same manner as in the case of dry ice seeding, and the fog is cleared.

Commercial airports have been cleared of supercooled fog for many years by dry ice seeding as a standard practice. Military airfields have been cleared by use of both propane and dry ice methods.

Warm fog is fog wherein the air temperature is above freezing. The aforementioned methods of seeding do not function in warm fog. Unfortunately, 95 % of all fogs are warm fogs that blanket airports, highways, and harbors. Warm fogs have been seeded with a variety of chemicals and agents in an attempt to clear, or at least to thin them. None has proven more than slightly successful. Ordinary table salt has proven to be the most useful, but it is corrosive and ecologically unacceptable. A variety of organic and inorganic chemicals in various combinations, with and without electrical charges, has been tried, but with only slight success. A very fine spray of water droplets that are highly charged electrically when injected into warm fog has some promise.

Helicopter downwash has been successful in a very limited number of cases. To be successful, the fog must be very shallow, and the air above the fog, both dry and warm. Exhaust plumes from jet engines have had some success in a number of European airports, notably at Orly (Paris).

Basically, however, the problem of warm fog clearing remains unsolved.

Specific Types of Fog

In addition to the types of fog already described, specific types include:

Advection fogs owe their existence to the flow of air from one type of surface to another. Surface temperature contrast between two adjacent regions is necessary for their formation. The usual type of advection fog is formed when relatively warm and moist air drifts over much colder land or water surfaces. Over land, examples of this type are found when moist air drifts over snow-covered areas; over water, when moist warm air drifts over currents of very cold water. The latter happens with southerly or easterly winds blowing from the Gulf Stream over the Labrador Current. Coastal and lake advection fog forms when warm and moist air flows offshore onto cold water

(summer), or when warm moist air flows onshore over cold or snow-covered land (winter).

Black Fog. In the United States, colloquial name given to a dense fog over Cape Cod, Massachusetts, especially in the vicinity of Chatham, on the "elbow" of the Cape.

Bora Fog. A dense "fog" caused when the bora lifts a spray of small drops from the surface of the sea. It is well developed on the coast of Norway when a bora-like fall wind descends from the Scandinavian mountains as a sudden storm from the east. See also **Bora** in the **Winds and Air Movement** article.

Frontal fogs, associated with fronts, can occur when (a) warm and cold air masses are mixed in a frontal zone; (b) air is suddenly cooled over moist ground; or (c) precipitation falls into cold stable air and raises the dew-point temperature. In the latter precipitation-type fog, the greater the temperature difference between the relatively warm rain (or snow) and the colder air layer, the more rapidly will the fog develop.

Ice fog (also called *ice-crystal fog* , *frozen fog* , *frost fog*, *frost flakes*, *air hoar*, *rime fog* , pogonip.) A type of fog composed of suspended particles of ice, partly ice crystals 20 to 100 μ m in diameter, but chiefly, especially when dense, droxtals 12–20 μ m in diameter. It occurs at very low temperatures, and usually in clear, calm weather in high latitudes. The sun is usually visible and may cause halo phenomena. Ice fog is rare at temperatures warmer than $-30\,^{\circ}$C ($-22\,^{\circ}$F), and increases in frequency with decreasing temperature until it is almost always present at air temperatures of $-45\,^{\circ}$C ($-49\,^{\circ}$F) in the vicinity of a source of water vapor. Such sources are the open water of fast-flowing streams or of the sea, herds of animals, volcanoes, and especially products of combustion for heating or propulsion. At temperatures warmer than $-30\,^{\circ}$C ($-22\,^{\circ}$F), these sources can cause steam fog of liquid water droplets, which may turn into ice fog when cooled.

Radiation fog is a major type produced over a land area when radiational cooling reduces the air temperature to or below its dewpoint. Thus, a strict radiation fog is a nighttime occurrence, although it may begin to form by evening twilight and often does not dissipate until after sunrise. It forms over land and not over water because water surfaces do not appreciably change their temperature during hours of darkness. Factors favoring the formation of radiation fog are 1) a shallow surface layer of relatively moist air beneath a dry layer and clear skies, and 2) light surface winds. It can be most confusing near sea coasts with cold coastal water. It can be difficult at times to differentiate between this and other types of fog, especially since nighttime cooling intensifies all fogs. Radiation fog is frequently and logically called ground fog, but in U.S. weather observing practice, the latter term is defined only with respect to the amount of sky that is obscured by the fog.

Steam fog (or *sea smoke*; also called *arctic sea smoke*, *Antarctic sea smoke, frost smoke, water smoke, sea mist, and steam mist*) is most commonly formed when very cold air drifts across relatively warm water. No matter what the nature of the vapor source (warm water, industrial combustion exhaust, breath), its equilibrium vapor pressure is greater than that which corresponds to the colder air. Thus, the water vapor, upon becoming mixed with and cooled by the cold air, rapidly condenses. It should be noted that this mechanism never allows the fog to actually reach the vapor source. Also, upon further mixing in sufficiently turbulent or convective flow (only a slight degree is needed), the fog particles evaporate at a more or less well defined upper limit of the fog. Note, also, that although advection of air is necessary to produce steam fog, it differs greatly from an advection fog in the usual sense, which is caused by warm, moist air moving over a cold surface. Steam fog is commonly observed over lakes and streams on cold autumn mornings as well as in Polar Regions. It is sometimes confused with ice fog, but its particles are entirely liquid. At temperatures below $-29\,^{\circ}$C ($-20\,^{\circ}$F), these may freeze into droxtals and create a type of ice fog that may be known as frost smoke.

Upslope fog is formed when air flows upward over rising terrain and is, consequently, adiabatically cooled to or below its dew point. It will form only in air that is convectively stable, never in air that is unstable, because instability permits the formation of cumulus clouds and vertical currents.

FOG DRIP. Water dripping to the ground from trees or other objects that have collected the moisture from drifting fog. In some instances the dripping is as heavy as light rain, as sometimes occurs among the redwood trees along the coast of northern California. During the foggy but almost rainless summers of California, fog drip prevents an excessive aridity in the coastal forests. As much as 0.05 in. of water, equivalent to a moderate shower, has been collected from a California fog in a single night. From the aerodynamic principles underlying the theory of collection efficiency it is clear that the needlelike leaves of conifers are better adapted to the removal of droplets from drifting fog than are the broad leaves of most deciduous trees. This characteristic may have been crucial in the evolutionary development of the redwoods in the limited areas wherein they thrive. Man-made fog-water collectors have been constructed in western Chile that utilize fog drip to provide water to the local population.

FOG TRACKS. Linear regions of condensation, produced in air or other gases that are supersaturated with water vapor, by the passage of electrified particles. Fog tracks are useful in following the courses and collisions of such particles.

FOKKER-PLANCK EQUATION. An equation originally occurring in the theory of diffusion when drift is taken into account. It may be written in the form

$$\frac{\partial v(x,t)}{\partial t} = -2c\frac{\partial v(x,t)}{\partial x} + D\frac{\partial^2 v(x,t)}{\partial x^2}$$

where $v(x,t)$ is the probability density for displacement x at time t, D is the diffusion coefficient and c represents drift. The equation occurs in the theory of stochastic processes as a limiting case of random walk or additive processes.

FOLIC ACID. [CAS: 59-30-3] Frequently identified with the other B vitamins, folic acid plays a number of important roles in human and animal biological systems. The substance, *pteroylmonoglutamic acid* or *folacin*, is involved in the synthesis of nucleic acid, in purine-pyrimidine metabolism, in serine-glycine conversion, in the differentiation of embryonic nervous systems, in one-carbon transfer mechanisms, in the metabolism of tyrosine and histidine, and in the synthesis of choline, among other biological processes. Folic acid is closely related to vitamin B_{12} (cobalamine) because of their interdependence in biological processes.

Dietary deficiencies of folic acid are most frequently associated with anemias (macrocytic, megaloblastic, and pernicious), glossitis, diarrhea, gastrointestinal lesions, intestinal malabsorption, and sprue.

Sources of Folic Acid. Neither folic acid nor vitamin B_{12} is produced by humans in adequate amounts; the substances must be absorbed from food. Natural sources of folic acid include:

High folic acid content (90–300 micrograms/100 grams)

Asparagus, dry beans (lentils, limas, navy), liver (beef, chicken, lamb, pork), spinach, wheat bran, yeast

Medium folic acid content

Beef kidney

Low folic acid content

Most fruits, nuts, vegetables, grains, and dairy products.

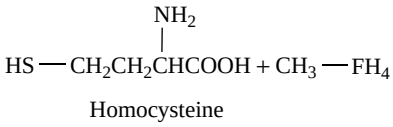
The substance is synthesized by bacteria in some vertebrates, including human, rat, dog, pig, and rabbit. Exogenous sources are required by most other vertebrates and invertebrates. In ruminants, synthesis of folic acid occurs in the rumen, but some researchers believe that newborn lambs require a dietary supplement. The most common manifestation of a deficiency in livestock is development of a characteristic macrocytic, hyperchromic anemia (also called megaloblastic anemia). Bone marrow changes, red cells are large and immature, usually with an accompanying reduction of white cell numbers. Folic acid deficiency in poultry retards growth.

Causes of Folic Acid Deficiency. These may be placed in four principal categories: (1) *inadequate intake* as the result of general *nutritional deficiencies* caused by food faddism or *alcoholism*; (2) *increased demand* of the body for folic acid in combination with inadequate intake, which may be the result of pregnancy, severe hemolysis (destruction of red blood cells), or chronic hemodialysis or peritoneal dialysis; (3) *inadequate absorption*, which may result from the presence of certain diseases, such as tropical sprue, gluten-sensitive enteropathy (nontropical sprue), Crohn's disease, lymphoma or amyloidosis of small bowel, diabetic enteropathy, and various intestinal procedures, such as resections or diversions; (4) *interference with folic acid metabolism*, as may result from blocking and interfering reactions of certain drugs, such as methotrexate, trimethoprim, pyrimethamine, phenytoin, ethanol (as in alcoholism), antituberculosis drugs, and possibly oral contraceptives (debatable among experts).

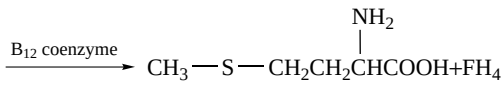
Replacement of Folic Acid. With so many causes of deficiency as just delineated, obviously replacement measures must be matched against the causes. A primary objective, where feasible, of course, is to remove or alleviate the causative factors. Also, where there are no contraindication factors, folic acid can be administered in therapeutic dosages. Very small dosages (1 mg orally per day) can often be effective.

Biochemistry. Folic acid coenzymes are derivatives of tetrahydrofolic acid. See also **Coenzymes**. Structurally, these are:

One-carbon fragments in various oxidation states are: (1) formyl (−CHO); (2) hydroxymethyl ($-CH_2OH$); and (3) methyl ($-CH_3$). The coenzyme forms of folic acid have one of these groups attached to either the 5-N or 10-N of tetrahydrofolic acid. One folic acid coenzyme, methyltetrahydrofolate (CH_3F-H_4) transfers in methyl group to homocysteine to yield methionine, in a reaction which also requires a vitamin B_{12} coenzyme:



Homocysteine



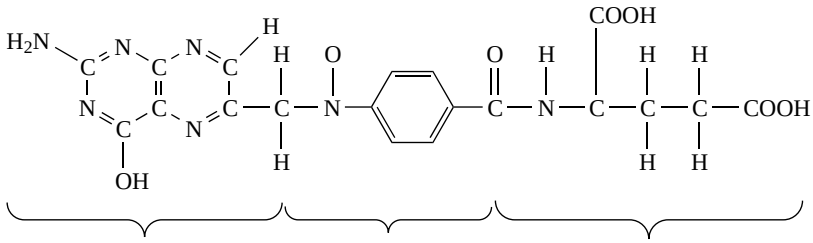
Methionine

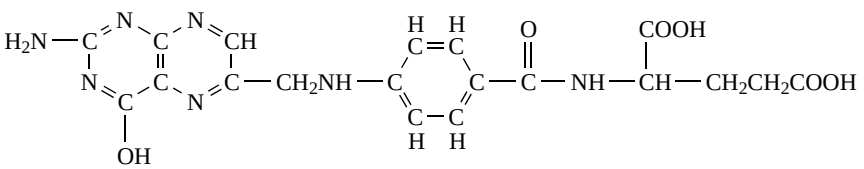
As pointed out by Chen and Cooper (Division of Food Science and Nutrition, California State University, Northridge, California), the group of compounds denoted by the term *folacin* is a heterogeneous group of derivatives with a similar basic structure and biological function. Folic acid is the basic structural unit in these compounds. Other monoglutamate folates are formed when the pteridine moiety of this basic molecule is reduced or substituted in the 5-N or 10-N position. In addition, all of these monoglutamate folates may be transformed into polyglutamates of various length by the addition of glutamic acid residues to the basic molecule.

Antagonists of folic acid include aminopterin (4-amino-pteroylglutamic acid), methotrexate (amethopterin), pyrimethamine, and 4-amino-pteroylaspartic acid. Synergists include biotin, pantothenic acid, niacin, vitamins B_1, B_2, B_6, B_{12}, C, and E, somatotrophin (growth hormone), and testosterone.

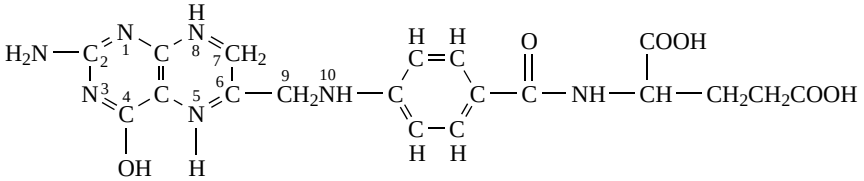
Bioavailability of Folic Acid. Factors which cause a decrease in bioavailability include: (1) high urinary excretion; (2) destruction by certain intestinal bacteria; (3) increased urinary excretion caused by vitamin C; (4) presence of sulfonamides which block intestinal synthesis; and (5) a decrease in absorption mechanisms. Increase in bioavailability can be provided by stimulating intestinal bacterial synthesis in certain species. No toxicity due to folic acid has been reported in humans.

Some of the unusual features of folic acid noted by investigators include: (1) folic acid antagonists used in cancer therapy with temporary remissions; (2) folic acid occurs in chromosomes; (3) folic acid is distributed throughout cells; (4) needed for mitotic step metaphase to anaphase; (5) antibody formation decreased in folic acid deficiency; (6) choline-sparing effects;





Folic acid



Tetrahydrofolic acid

(7) analgesic in humans — pain threshold is increased; (8) antisulfonamide effects; (9) enterohepatic circulation of folate; (10) synthesized by psittacosis virus; (11) concentrated in spinal fluid.

Historical Perspective. Over the years, folic acid has been variously referred to as vitamin B_c, vitamin M, and the *L. casei* factor.

In 1931, Wills demonstrated a factor from yeast active in treating anemia. In 1938, Day et al. found yeast or liver extracts active in treating anemia in monkeys. Hogan and Parrot, in 1939, showed how anemia in chicks could be prevented by using liver extract. The *L. casei* growth factor was isolated from liver and yeast by Snell and Peterson in 1940. Hutchings et al., in 1941, found the *L. casei* factor also essential for chicks. Also, in 1941, Mitchell, Snell, and Williams isolated bacterial (*S. lactis* R.) growth factor similar to *L. casei* factor from yeast and named the substance folic acid. Stokstad, in 1943, reported *L. casei* factor from liver more active than from yeast; and provided evidence of multiple factors. Pteroylmonoglutamic acid was finally isolated, the structure proved, and the substance synthesized by Angier et al. in 1946. Commercial production of folic acid is either by extraction from yeast or liver, or by synthesis wherein 2,3-dibromopropanol, 2,4,5-triamino-6-hydroxypyrimidine, and para-aminobenzoyl glutamic acid are reacted.

Folic Acid Assay. Deficiencies of folic acid and vitamin B_{12} are relatively common. Whenever macrocytic anemia is present, evaluation of these two vitamins is necessary to determine the cause of the condition. The standard method of measuring folic acid has been the microbiological assay (Bailey et al., 1982), which can be used to measure folic acid in serum, blood, tissues, and foods. Improved high performance liquid chromatography (HPLC) methods have simplified differential analysis of the metabolites of folic acid (Shane, 1982), but low percent recovery is compounded by the degree of glutamate conjugation.

The evaluation of folic acid status must often also include evaluation of vitamin B_{12} because of its effect on folate metabolism. A vitamin B_{12}-dependent reaction is necessary for an enzyme involved in the catabolism of branched-chain amino acids (methylmalonyl CoA to succinyl CoA). This reaction may provide the basis for a functional assessment method for vitamin B_{12} status. See also **Hormones**; and **Vitamin**.

FOLIUM OF DESCARTES. A higher plane curve, which is a special case of a cissoid, defined by the equation

$$x^2 + y^3 = axy$$

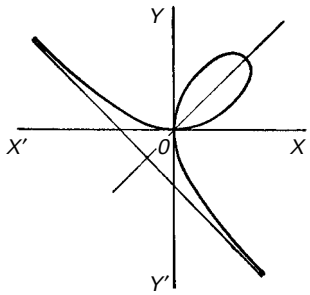

Fig. 1. Folium of Descartes.

or in parametric form by $(1 + t^3)x = at$; $(1 + t^2)$. The coordinate origin is a node for the curve and the coordinate axes are the two corresponding tangents. The asymptote to its two infinite branches is $3(x + y) + a = 0$. See Fig. 1.

See also **Curve (Higher Plane)**.

FOLLICLE. In zoology, a glandular cavity or sac. The small spherical chambers in the thyroid gland, the hair follicle, the fluid-filled cavity in the vertebrate ovary in which the ovum develops, and the chambers of the arthropod testis are examples of the application of the term.

FOLLICLE CELL. Cells of the ovarian follicle that nourish the ovum during its development. They occur in the Graafian follicles of vertebrates and in the open follicles of invertebrates. In the insects, specialized cells of similar function contained within the follicle are termed nurse cells.

FOLLICULITIS. Folliculitis is the name given to a group of skin conditions in which there are inflamed hair follicles. The result is a tender red spot, often with a surface pustule. Folliculitis can be due to infection, occlusion, irritation and specific skin diseases. Most infections are superficial, and although they may itch, they are seldom painful. Superficial folliculitis often clears by itself in a few days, but deep or recurring folliculitis may need medical treatment.

The most common cause of folliculitis is due to *staphylococcus aureus*, a type of bacteria. Some of the predisposing factors include an infected wound elsewhere on the body, poor personal hygiene, diabetes mellitus, occlusive cosmetics, tight clothing or hats, exposure to chemicals and a decreased immune system.

This disorder may be recurrent and troublesome. Folliculitis may lead to furunculosis, and if left untreated, it may lead to cellulitis (a more extensive inflammation of the skin). Abscess formation is the major complication of bacterial folliculitis. See also **Abscess**; and **Cellulitis**.

The signs and symptoms of folliculitis vary, depending on the type of infection. In superficial forms of the disorder, small pimples develop around one or more hair follicles. One way to distinguish a follicular pimple from acne is that with a follicular pimple me often can see the hair shaft at the center of the lesion. The pimples sometimes contain pus (pustules), and they may crust over or be surrounded by an area that is red and inflamed. The infection may itch or be somewhat tender, but it usually is not painful. Deep folliculitis, which affects the entire hair follicle, can cause more severe signs and symptoms, including large, painful, pus-filled pimples that may leave scars when they heal.

Superficial Folliculitis

Superficial forms of folliculitis include:

Pseudomonas Folliculitis (Hot Tub Folliculitis). The pseudomonas bacteria (*Pseudomonas aeruginosa*) that cause this form of folliculitis thrive in a wide range of environments, including wooden hot tubs whose chlorine and pH levels aren't well regulated. About 12 to 48 hours after being exposed to the bacteria, one is likely to develop a number of red, round, itchy bumps that later may develop into small pus-filled blisters (pustules). The rash is likely to be worse in areas where a swimsuit holds contaminated water against the skin. One is at increased risk of infection if, a one is diabetic has history of skin infections, has or open cuts or sores.

Hot tub folliculitis rarely requires treatment, although a doctor may prescribe an oral or topical medication to help relieve itching (anti-pruritic). More serious cases may require an oral antibiotic.

Barber's Itch. This type of folliculitis is marked by itchy, white, pus-filled lumps in the beard area in men and sometimes on the legs or underarms in women. It occurs when hair follicles that have been irritated by shaving become infected with *Staphylococcus aureus* (staph) bacteria. Although staph bacteria live on the skin all the time, they generally cause problems only when they enter the body through a cut or other wound.

Typical treatment prescribed by a doctor is not shaving the affected area until the infection heals. If shaving is necessary, use an electric razor or clean razor blade every time. If the problem persists, topical or oral antibiotics may be needed.

Tinea Barbae. Caused by a fungus rather than a bacterium, this type of folliculitis also develops in the beard area in men. Like barber's itch, tinea barbae causes itchy, white bumps. The surrounding skin also may become reddened. A more serious, inflammatory form of the infection appears as pus-filled nodules that eventually form a crust and that may occur along with swollen lymph nodes and fever.

This infection — especially the inflammatory form — can be effectively treated with oral antifungal medications.

Pseudofolliculitis Barbae. An inflammation of the hair follicles in the beard area, pseudofolliculitis barbae affects men with curly beards. It develops when shaved hairs curve back into the skin, leading to inflammation and, in rare cases, to dark raised scars (keloid scars) on the face and neck.

The best treatment for this condition is preventive. Shaving with an electric razor, which does not cut as closely as a razor blade does, can help. If a blade is used, massage the beard area with a warm, moist washcloth or facial sponge to lift the hairs so they can be cut more easily. Use a shaving gel instead of cream, and shave in the direction of the hair growth. When done, rinse thoroughly with warm water and apply a moisturizing after-shave. If these measures do not help, a doctor may prescribe the acne medication tretinoin (Retin-A).

Pityrosporum Folliculitis. Especially common in young and middle-aged adults, pityrosporum folliculitis produces chronic, red, itchy pustules on the back and chest and sometimes on the neck, shoulders, upper arms and face. It is caused by infection with a yeast-like fungus, Malassezia furfur, which is similar to the fungus that causes dandruff, although the pustules closely resemble acne.

Topical or oral antifungals are the most effective treatments for this type of folliculitis. Because the condition often returns once the course of oral medication is finished, a doctor may recommend using topical ointments indefinitely. Antibiotics are not helpful in treating pityrosporum folliculitis and may make the infection worse by upsetting the normal balance of bacteria on your skin.

Herpetic Folliculitis. Shaving through a cold sore — a small, fluid-filled blister caused by the herpes simplex virus — can sometimes spread the herpes infection to neighboring hair follicles.

If one is a healthy adult, herpetic folliculitis may clear without treatment in seven to 10 days. But those living with HIV/AIDS or one experiences frequent cold sores, a doctor may prescribe an oral antiviral medication such as acyclovir, famciclovir or valacyclovir. Although these drugs can clear the infection, they will not necessarily prevent it from recurring. They also may cause side effects such as headache, diarrhea, nausea and abdominal pain.

Deep Folliculitis

Types of deep folliculitis include:

Gram-Negative Folliculitis. This sometimes develops in people receiving long-term antibiotic treatment for acne. Antibiotics alter the normal balance of bacteria in the nose, leading to an overgrowth of harmful organisms (Gram-negative bacteria). In most people, this does not cause problems, and the flora in the nose returns to normal once antibiotics are stopped. In a few people, however, Gram-negative bacteria spread to the cheeks, chin and jaw line, where they cause new, sometimes-severe acne lesions.

The term *Gram negative* refers to the staining pattern of the organisms in the laboratory. Certain bacteria do not take up a stain known as *Gram*.

Although this type of folliculitis results from long-term antibiotic therapy for acne, it is usually treated with certain antibiotics or with isotretinoin (Accutane).

Boils and Carbuncles. These occur when hair follicles become deeply infected with staph bacteria. A boil usually appears suddenly as a painful pink or red bump about 1/2 inch (1.25 cm) in diameter. The surrounding skin also may be red and swollen. Within 24 hours, the bump fills with pus. It grows larger and more painful for five to seven days, sometimes reaching golf-ball size before it develops a yellow-white tip that finally ruptures and drains. Boils generally clear completely in about two weeks. Small boils usually heal without scarring, but a large boil may leave a scar. A carbuncle is a cluster of boils that often occurs on the back of the neck, shoulders or thighs, especially in older men. Carbuncles cause a deeper and more severe infection than a single boil. As a result, they develop and heal more slowly and are likely to leave scars.

A doctor may drain a large boil or carbuncle by making a small incision in the tip. This relieves pain, speeds recovery and helps lessen scarring. Deep infections that cannot be completely cleared may be covered with sterile gauze so that pus can continue to drain. Sometimes a doctor may prescribe antibiotics to help heal severe or recurrent infections.

Eosinophilic Folliculitis. Seen primarily in HIV-positive people, this type of folliculitis is characterized by recurring patches of inflamed, pus-filled sores, primarily on the face and sometimes on the back or upper arms. The sores usually spread, may itch intensely and often leave areas of darker than normal skin (hyperpigmentation) when they heal. The exact cause of eosinophilic folliculitis is not known, although it may involve the same yeast-like fungus responsible for pityrosporum folliculitis.

A number of therapies are effective against eosinophilic folliculitis, but topical corticosteroids are often the treatment of choice. A doctor may prescribe a short course of oral corticosteroids if one has a severe infection. All steroids can have serious side effects and should be used for as brief a time as possible. For HIV/AIDS patients with mild eosinophilic folliculitis, a doctor may prescribe topical steroids in conjunction with oral antihistamines. More severe cases may require treatment with isotretinoin (Accutane) for several months.

Staff: *Folliculitis - a Medical Dictionary, Bibliography, and Annotated Research Guide to Internet References*, Icon Health Publications, San Diego, CA, 2004.

FOMALHAUT (α Piscis Austrini). The southernmost first magnitude star visible from the latitude of New York. Formalhaut rises almost simultaneously with Capella and is above the southern horizon during the evening in the autumn months. It was one of the royal stars of astrology, ruling over the southern sky. Ranking eighteenth in apparent brightness among the stars, Fomalhaut has a true brightness value of 14 as compared with unity for the sun. Fomalhaut is a white, spectral type A star and is located in the constellation Pisces Austrinus south of the ecliptic. Estimated distance from the earth is 23 light years. See also **Constellations**.

FONTANELLE. Any one of the places in an infant's skull that have not become bony at birth. These places are usually situated at each of the angles of the two parietal bones. By the age of 14 months, the anterior fontanelle is, from the functional standpoint, closed, and is the last to become so. Fontanelles also occur in the skulls of other vertebrates, in their immature form.

FOOD ADDITIVES. A food additive is any substance that becomes part of a food product either directly or indirectly during some phase of processing, storage, or packaging.

Direct food additives are those that have been intentionally added to food for functional purpose, in controlled amounts, usually at low levels (from parts per million, ppm, to 1–2% by weight). Basic foodstuffs are excluded from the definition, although ingredients that are added to foods (eg, high fructose corn syrup, starches, and protein concentrates) are often included among food additives.

Included in the direct food additive category are

- Inorganic chemicals — phosphates, sulfates, nitrates, etc.
- Synthetic chemicals — dyes, silicones, benzoates, vitamin A, etc.
- Extraction products from natural sources — essential oils, gums, vitamin E, etc.
- Fermentation derived products — enzymes, lactic acid, citric acid, etc.

Indirect or nonintentional additives on the other hand, are those entering into food products in small quantities as a result of growing, processing,

or packaging. Examples of these are lubricating oils from processing equipment or components of a package that migrate into the food before consumption.

The difference between food additives and ingredients is mainly in the quantity used in any given formulation. Food ingredients can be consumed alone as food (eg, butter, sucrose), while food additives are mainly used in small quantities relative to the total food consumption but which nonetheless play a large part in the production of desirable and safe food products.

The practice of adding chemicals (eg, salt, spices, herbs, vinegar, and smoke) to food dates back many centuries. In recent years, however, the ubiquitous presence of chemical additives in processed foods has attracted much attention and public concern over the long-term safety of additives to humans. Although the safety issue is far from subsiding, there is scientific consensus that food additives are indispensable in the production, processing, and marketing of many food products, and that the judicious use of chemical additives — typically in the range from a few ppm to <1% by weight of the finished food — contributes to the abundance, variety, stability, microbiological safety, flavor, and appearance of the food supply. While food additives offer a major contribution to the palatability and appeal of a wide variety of foods, their level of use is relatively insignificant in the total human diet.

Government Regulations

According to the *U.S. Code of Federal Regulations*, food additives may be defined as "substances ... the intended use of which results or may reasonably be expected to result, directly or indirectly, either in their becoming a component of food or otherwise affecting the characteristics of food" (*Title 21, Part 170.3*, Apr. 1, 1990). Canada and the European Community have adopted similar definitions. According to this broad definition, a food additive is synonymous to a food ingredient. In practice, however, the word additive is limited to substances that are used in small quantities.

In the United States, substances permitted in food and beverages are regulated by the U.S. Food and Drug Administration (FDA), an agency of the Department of Health and Human Services. Additives used in meat and poultry are regulated by the U.S. Department of Agriculture, and additives for alcoholic beverages are regulated by the Bureau of Alcohol, Tobacco and Firearms of the U.S. Department of Treasury. Premarketing approval is required.

In the United States, additional ramifications may be expected from FDA's announcement of final regulations for new food labeling requirements under the directive of the Nutrition Labeling and Education Act of 1990. Among other things, these regulations limit health claims that can be made on food labels. They also require new information on nutrient content, and limit the use of descriptors such as low and free in association with calories, fat levels, and other food product characteristics.

In Europe, the formation of the European Economic Community has created a requirement to bring food additive approvals of the member nations into alignment, so as to eliminate differences in laws that hinder the movement of foodstuffs among these nations.

Classes of Food Additives

Acidulants, the most versatile and widely used ingredients in the food industry, function well as flavoring agents. They include adipic acid [CAS: 124-04-9], citric acid [CAS: 77-92-9], fumaric acid [CAS: 110-17-8], gluconolactone [CAS: 90-80-2], lactic acid [CAS: 50-21-5], malic acid [CAS: 6915-15-7], phosphoric acid [CAS: 7664-38-2], and tartaric acid [CAS: 87-69-4]. See also **Acidulants and Alkalizers (Foods)**.

Anticaking agents function by absorbing excess moisture, or by coating particles and making them water repellent. They include calcium silicate [CAS: 1344-95-2], $CaSiO_3$, and calcium and magnesium salts of long-chain fatty acids, such as calcium stearate [CAS: 1592-23-0], $C_{36}H_{70}CaO_4$. See also **Anticaking Agents**.

Polydimethylsiloxane, or silicone, is used at a level of approximately 10 parts per million to control foam in food products as antifoaming agents.

Antioxidants work by donating a hydrogen atom to the reactive peroxide radical, ending the chain reaction. Both synthetic and natural antioxidants exist. The most commonly used synthetic antioxidants include butylated hydroxyanisole [CAS: 25013-16-5] (BHA), $C_{11}H_{16}O_2$, butylated hydroxytoluene [CAS: 128-37-0] (BHT), $C_{15}H_{24}O$, propyl gallate [CAS: 121-79-9] (PG), $C_{10}H_{12}O_5$, and *tert*-butylhydroquinone [CAS: 1948-33-0] (TBHQ), $C_{10}H_{14}O_2$. Although BHT was never removed from the GRAS list, continuing concern over its safety has resulted in decreased usage.

The most popular natural antioxidants on the market are rosemary extracts and tocopherols. Certain compounds, known as chelating agents, react synergistically with many antioxidants. Citric acid and ethylenediaminetetraacetic acid (EDTA), $C_{10}H_{16}N_2O_8$, are the most common chelating agents used.

Another group of compounds called oxygen scavengers retard oxidation by reducing the available molecular oxygen. Products in this group are water soluble and include erythorbic acid [CAS: 89-65-6], $C_6H_8O_6$, and its salt sodium erythorbate [CAS: 6381-77-7], $C_6H_7O_6Na$, ascorbyl palmitate [CAS: 137-66-6], $C_{22}H_{38}O_7$, ascorbic acid (Vitamin C) [CAS: 50-81-7], $C_6H_8O_6$, glucose oxidase [CAS: 9001-37-0], and sulfites [CAS: 14265-45-3]. See also **Antioxidants**.

Bulking agents are substances that add bulk to food products while contributing fewer calories than the ingredients they replace.

Polydextrose, a polymer of glucose that contains traces of sorbitol and citric acid, is the most widely used soluble bulking agent in the United States.

Low calorie bulking agents represent an ingredient category having a great deal of potential, and several companies are developing products. The most common are naturally derived polymers of glucose and other sugars (polydextrose falls into this category), enantiomers of natural sugars, or synthetic polymers. Bulking sweeteners provide a bulking effect, along with some of the sweetness and functional properties of sugar. Products that fall into this category include mannitol, [CAS: 87-78-5] $C_6H_{14}O_6$, isomaltitol, some L-sugars, and fructooligosaccharides. See also **Bodying and Bulking Agents (Foods)**; and **Sweeteners**.

According to U.S. regulations, colorants are divided into two classes: certified and exempt. The FD&C certified colors are all water-soluble dyes, but can be transformed into insoluble pigments known as lakes by precipitating the dyes with aluminum, calcium, or magnesium salts on a substrate of aluminum hydroxide.

Exempt colors do not have to undergo formal FDA certification requirements, but are monitored for purity. The colorants exempt from FD&C certification are annatto extract, β-carotene, beet powder, β-apo$-8'$-carotenol, canthaxanthin, caramel, carmine, carrot oil, cochineal extract, cottonseed flour, ferrous gluconate, fruit juices, grape skin extract, paprika, paprika oleoresin, riboflavin, saffron, titanium dioxide, turmeric, turmeric oleoresin, ultramarine blue, and vegetable juices. See also **Colorants (Foods)**.

Dietary fiber is a broad term that encompasses the indigestible carbohydrate and carbohydrate-like components of foods that are found predominantly in plant cell walls. It includes cellulose lignin, hemicelluloses, pentosans, gums, and pectins. See also **Carbohydrates**; and **Dietary Fiber**.

The chemical structures of emulsifiers, or surfactants, enable these materials to reduce the surface tension at the interface of two immiscible surfaces, thus allowing the surfaces to mix and form an emulsion. An emulsifier consists of a polar group, which is attracted to aqueous substances, and a hydrocarbon chain, which is attracted to lipids. Emulsifiers include mono- and diglycerides, lecithin, propylene glycol esters, lactylated esters, sorbitan and sorbitol esters, polysorbates, and sucrose esters.

In the food industry, the largest use of enzymes is in starch processing, cheese production, fruit and vegetable juice processing, baking, and brewing. Commercial enzyme preparations are obtained from animals and plants via extraction, or through cultivation of select microorganisms. Enzymes are divided into six main classes: hydrolases, isomerases, ligases, lyases, oxidoreductases, and transferases. See also **Enzyme**.

Two classes of fat replacers exist: mimetics, which are compounds that help replace the mouthfeel of fats but cannot substitute for fat on a weight for weight basis; and substitutes, compounds having physical and thermal properties similar to those of fat, that can theoretically replace fat in all applications. Because fats play a complex role in so many food applications, one fat replacer is often not a satisfactory substitute. Thus a systems approach to fat replacement, which relies on a combination of emulsifiers, gums, and thickeners, is often used.

Existing fat mimetics are either carbohydrate-, cellulosic (fiber)-, protein-, or gum-based.

During thermal processing and freezing, the bonds of pectic substances in plant walls that help to stabilize structure are modified, resulting in an unacceptably soft product. The cell wall structure of fruits and vegetables can be strengthened by adding polyvalent cations that promote the cross-linking of the free-carboxyl groups of pectic substances. Fruits such as

tomatoes, berries, and apple slices are commonly firmed by added calcium salts prior to processing. Acidic aluminum salts are added during the preparation of pickles and relishes to provide the same effect. See also **Firming Agents (Foods)**.

Flavorings are used in the food industry to replace or enhance flavors that are lost during processing, to create flavor combinations that do not exist in nature, and to mask objectionable flavors. Over 6000 flavor ingredients exist. They include essential oils, oleoresins, fruit juices and concentrates, botanical and animal extracts, aroma chemicals, and compounded flavors. See also **Flavors and Essences**.

Flavor enhancers have the ability to enhance flavors at a level below which they contribute any flavor of their own. Worldwide, the most popular flavor enhancers are monosodium L-glutamate [CAS: 142-47-2] (MSG), $NaC_5H_8NO_4$, and the 5′-ribonucleotides: disodium 5′-inosinate (IMP), $C_{10}H_{11}N_4O_8P \cdot 2$ Na, and disodium 5′-guanylate (GMP), $C_{10}H_{12-}N_5O_8P \cdot 2$ Na.

Ammonium glycyrrhizinate (AG), $C_{42}H_{65}NO_{16}$, is a flavor enhancer derived from licorice root. Maltol [CAS: 118-71-8], $C_6H_6O_3$, and ethyl maltol [CAS: 4940-11-8], $C_7H_8O_3$, are used as flavor enhancers in products such as cake mixes, confections, cookies, ice cream, fruit juices, puddings, and beverages.

Benzoyl peroxide [CAS: 94-36-0], $C_{14}H_{10}O_4$, is a bleaching agent that is typically added at the flour mill at a level between 0.015 and 0.075%. This additive oxidizes the carotenoid pigments, resulting in a white flour. Gases that exert an effect on the flour upon immediate contact include chlorine gas, chlorine dioxide [CAS: 10049-04-4], ClO_2, nitrosyl chloride [CAS: 2696-92-6], NOCl, nitrogen oxides, N_xO_x, and nitrogen tetroxide [CAS: 10102-44-0], N_2O_4. Others that exert their effect when the flour is made into dough include potassium bromate [CAS: 7758-01-2], $KBrO_3$ potassium bromate, KlO_3, calcium iodate [CAS: 7789-80-2], $Ca(IO_2)_3$, and calcium peroxide [CAS: 1305-79-9], CaO_2.

Formulation acids, which include carriers, binders, fillers, plasticizers, and film-formers, are ingredients used in processing to impart a particular physical state or textural characteristic.

Fumigants are volatile substances used for controlling insects or pests. They include ethylene oxide [CAS: 75-21-8], C_2H_4O, propylene oxide [CAS; 75-56-9], C_3H_6O, and methyl bromide [CAS: 74-83-9], CH_3Br. See also **Pesticides**.

Gases provide three basic functions as food ingredients: preservation, carbonation, and aeration.

In certain foods, it is necessary to control the amount of water that enters or exits the product. It is for this purpose that humectants are employed. Polyhydric alcohols (polyols), which include propylene glycol [CAS: 57-55-6], $C_3H_8O_2$, glycerol [CAS: 56-81-5], $C_3H_8O_3$, sorbitol [CAS: 50-70-4], $C_6H_{14}O_6$, and mannitol [CAS: 87-78-5] $C_6H_{14}O_6$, contain numerous hyroxyl groups. Their structure makes them hydrophilic and enables them to bind water in foods. See also **Humectants and Moisture-Retaining Agents**.

Sodium bicarbonate [CAS: 144-55-8], $NaHCO_3$, is the most commonly used product, but ammonium bicarbonate [CAS: 1066-33-7], NH_4HCO_3, and potassium bicarbonate [CAS: 298-14-6], $KHCO_3$, are used as well. When used alone, sodium bicarbonate reacts to give products a bitter, soapy flavor. Thus it is always combined with a leavening acid.

Leavening acids are classified according to the rate at which they release carbon dioxide from sodium bicarbonate. Most products use both slow- and fast-acting leavening acids to obtain appropriate volume. The leavening acids most frequently used include potassium acid tartrate, sodium aluminum sulfate, δ-gluconolactone, and ortho- and pyrophosphates. See also **Leavening Agents**.

Ingredients that fall into this category include oils, lecithin, starch, distilled acetylated monoglycerides, and magnesium silicate, $MgSiO_3$. See also **Lubricating Agents**.

As of this writing there are only three nonnutritive sweeteners approved for used in the United States: aspartame [CAS: 22839-47-0], $C_{14}H_{18}N_2O_5$, saccharin [CAS: 81-07-2], $C_7H_5NO_3S$, and acesulfame K [CAS: 33665-90-6], $C_4H_5NO_4S \cdot K$. See also **Sweeteners**.

In the United States, foods are either restored, enriched, or fortified with nutrients. The enrichment program followed in the United States is *(1)* the enrichment of flour, bread, and degerminated and white rice using thiamin [CAS: 59-43-8], $C_{12}H_{17}N_5O_4S$, riboflavin [CAS: 83-88-5], $C_{17}H_{20}N_4NaO_9P$, niacin [CAS: 59-67-6], $C_6H_5NO_2$, and iron [CAS: 7439-89-6]; *(2)* the retention or restoration of thiamin, riboflavin, niacin, and iron in processed food cereals; *(3)* the addition of vitamin D to milk, fluid skimmed milk, and nonfat dry milk; *(4)* the addition of vitamin A, $C_{20}H_{30}O$, to margarine, fluid skimmed milk, and nonfat dry milk; *(5)* the addition of iodine to table salt; and *(6)* the addition of fluoride to areas in which the water supply has a low fluoride content. See also **Vitamin** and its family of articles.

Most preservatives do not kill microorganisms present in food. Rather, they prevent further growth and proliferation of anything that is present by either lowering the water activity or increasing the pH of the foods in which they are used. Preservatives include benzoates, sorbates, propionates, organic acids, sulfur dioxide and sulfites, parabens, sodium nitrate and sodium nitrites, and natamycin and nisin. See also **Preservative**.

Manufacturing aids used to improve the appearance or performance of food products include clarifying agents (flocculants), clouding agents, catalysts, and filter aids. See also **Flocculating Agents**.

Solvents are generally used to either extract particular compounds, such as an essential oil from a plant, or to carry additives into a food system, such as a flavor into a powdered mix. Common solvents include ethanol, C_2H_6O, glycerine $C_3H_8O_3$, propylene glycol, $C_3H_8O_2$, triethyl citrate, $C_{12}H_{20}O_7$, polyhydric alcohols, carbon dioxide, acetylated monoglycerides, hexane, C_6H_{14}, methylene chloride, CH_2Cl_2, acetone, C_3H_6O, and trichloroethylene, C_2HCl_3. See also **Solvent**.

Many food products receive their textural properties from a group of compounds known as hydrocolloids. Hydrocolloids fall into two classes: polysaccharides and proteins. They include locust bean gum, guar gum, gum arabic, carrageenan, xanthan gum, cellulose, agar, starch, pectin, alginates, and gelatin. See also **Stablizer**.

FOODBORNE DISEASES. A disease caused by consuming contaminated foods or beverages. Many different disease-causing microbes, or pathogens, can contaminate foods, so there are many different foodborne infections. In addition, poisonous chemicals or other harmful substances can cause foodborne diseases if they are present in food.

In most countries with well-developed health care systems, foodborne diseases fall within the province of public health authorities. Organizational structure varies from one country to the next, but usually the enforcement of regulations and collection of statistics is accomplished at the local level. Superimposed over city, county, and state or provincial agencies will be various national organizations — as, in the United States, the Public Health Service, the Center for Disease Control, and the Food and Drug Administration. The general absence of catastrophic outbreaks of foodborne diseases in many countries is testimony of the workability of the system and of the progress that has been made over the years. Control over food processors has been quite effective. It is not surprising, then, that a significant part of the foodborne disease problem remaining arises from actions taken by persons who are less experienced and inadequately aware of foodborne pathogens and poisons. An example is the home canner or the gracious host who inadvertently serves slowly warmed-over turkey at a community picnic that has been delayed several days because of inclement weather.

It is logical that the first interest in foods as means for transmitting communicable diseases would be concentrated on the main killers of earlier times. In the 1850s, it was found that water and milk were responsible for the spread of cholera and typhoid fever. Although they could not grow the organisms in the laboratory at that time, investigators did develop epidemiological evidence. Early interest concentrated on the association of human sewage with drinking water and foods, and other sources of the microorganisms were overlooked for many years. As comparatively recently as the 1920s, one public health pioneer insisted that animals were

the prime reservoir of salmonellae (except for *S. typhi* and most of the paratyphoid bacilli). Today, it is recognized that there is a high rate of excretion of salmonellae among poultry, swine, and cattle, that not all abattoirs can control the spread of infection from gut contents to meat, and that cross contamination from raw to cooked foods in food-preparation areas is responsible for a large proportion of foodborne salmonellosis. Thus, it turns out that animal sewage is far more important than is human sewage in the search for the source of an infective agent. Commercial interests militated against the confirmation that the heedless preparation of animal feeds from contaminated raw materials resulted in salmonella excretion in poultry and livestock.

More than 250 different foodborne diseases have been described. Most of these diseases are infections, caused by a variety of bacteria, viruses, and parasites that can be foodborne. Other diseases are poisonings, caused by harmful toxins or chemicals that have contaminated the food, for example, poisonous mushrooms. These different diseases have many different symptoms, so there is no one "syndrome" that is foodborne illness. However, the microbe or toxin that enters the body through the gastrointestinal tract often causes the first symptoms of nausea, vomiting, abdominal cramps and diarrhea.

Many microbes can spread in more than one way, so we cannot always know that a disease is foodborne. The distinction matters, because public health authorities need to know how a particular disease is spreading to take the appropriate steps to stop it. For example, *Escherichia coli* O157:H7 infections can spread through contaminated food, contaminated drinking water, contaminated swimming water, and from toddler to toddler.

Common Foodborne Diseases

The most commonly recognized foodborne infections are those caused by the bacteria *Campylobacter*, *Salmonella*, and *E. coli* O157:H7, and by a group of viruses called calicivirus, also known as the Norwalk and Norwalk-like viruses.

Campylobacter is a bacterial pathogen that causes fever, diarrhea, and abdominal cramps. It is the most commonly identified bacterial cause of diarrheal illness in the world. These bacteria live in the intestines of healthy birds, and most raw poultry meat has *Campylobacter* on it. Eating undercooked chicken, or other food that has been contaminated with juices dripping from raw chicken is the most frequent source of this infection.

Salmonella is also a bacterium that is widespread in the intestines of birds, reptiles and mammals. It can spread to humans, via a variety of different foods of animal origin. The illness it causes, salmonellosis, typically includes fever, diarrhea and abdominal cramps. In persons with poor underlying health or weakened immune systems, it can invade the bloodstream and cause life-threatening infections.

E. coli O157:H7 is a bacterial pathogen that has a reservoir in cattle and other similar animals. Human illness typically follows consumption of food or water that has been contaminated with microscopic amounts of cow feces. The illness it causes is often a severe and bloody diarrhea and painful abdominal cramps, without much fever. In 3% to 5% of cases, a complication called hemolytic uremic syndrome (HUS) can occur several weeks after the initial symptoms. This severe complication includes temporary anemia, profuse bleeding, and kidney failure.

Calicivirus, or Norwalk-like virus is an extremely common cause of foodborne illness, though it is rarely diagnosed because the laboratory test is not widely available. It causes an acute gastrointestinal illness, usually with more vomiting than diarrhea, that resolves within two days. Unlike many foodborne pathogens that have animal reservoirs, it is believed that Norwalk-like viruses spread primarily from one infected person to another. Infected kitchen workers can contaminate a salad or sandwich as they prepare it, if they have the virus on their hands. Infected fishermen have contaminated oysters as they harvested them.

Some common diseases are occasionally foodborne, even though they are usually transmitted by other routes. These include infections caused by *Shigella*, hepatitis A, and the parasites *Giardia lamblia* and *Cryptosporidia*. Even strep throats have been transmitted occasionally through food.

In addition to disease caused by direct infection, some foodborne diseases are caused by the presence of a toxin in the food that was produced by a microbe in the food. For example, the bacterium *Staphylococcus aureus* can grow in some foods and produce a toxin that causes intense vomiting. The rare but deadly disease botulism occurs when the bacterium *Clostridium botulinum* grows and produces a powerful paralytic toxin in foods. These toxins can produce illness even if the microbes that produced them are no longer there.

Other toxins and poisonous chemicals can cause foodborne illness. People can become ill if a pesticide is inadvertently added to a food, or if naturally poisonous substances are used to prepare a meal. Every year, people become ill after mistaking poisonous mushrooms for safe species, or after eating poisonous reef fishes.

The spectrum of foodborne diseases is constantly changing. A century ago, typhoid fever, tuberculosis and cholera were common foodborne diseases. Improvements in food safety, such as pasteurization of milk, safe canning, and disinfection of water supplies have conquered those diseases. Today other foodborne infections have taken their place, including some that have only recently been discovered. For example, in 1996, the parasite *Cyclospora* suddenly appeared as a cause of diarrheal illness related to Guatemalan raspberries. These berries had just started to be grown commercially in Guatemala, and somehow became contaminated in the field there with this unusual parasite. In 1998, a new strain of the bacterium *Vibrio parahemolyticus* contaminated oyster beds in Galveston Bay and caused an epidemic of diarrheal illness in persons eating the oysters raw. The affected oyster beds were near the shipping lanes, which suggested that the bacterium arrived in the ballast water of freighters and tankers coming into the harbor from distant ports. Newly recognized microbes emerge as public health problems for several reasons: microbes can easily spread around the world, new microbes can evolve, the environment and ecology are changing, food production practices and consumption habits change, and because better laboratory tests can now identify microbes that were previously unrecognized.

In the last 15 years, several important diseases of unknown cause have turned out to be complications of foodborne infections. For example, we now know that the Guillain-Barre syndrome can be caused by *Campylobacter* infection, and that the most common cause of acute kidney failure in children, hemolytic uremic syndrome, is caused by infection with *E. coli* O157:H7 and related bacteria. In the future, other diseases whose origins are currently unknown may turn out be related to foodborne infections.

Classification of Foodborne Diseases

1. **Poisonings** are caused by consuming toxicants which are found in tissues of certain plants and animals, metabolic products (toxins) formed and excreted by microorganisms (bacteria, fungi, algae) while they multiply in foods; or poisonous substances which may be intentionally added (but not later removed) or incidentally added to foods as a result of production, processing, transporting, and storing. See also **Food Toxicants, Naturally Occurring**.
2. **Infections** are caused by the entrance of pathogenic microorganisms into the body and the reaction of body tissues to their presence, or to the toxins which they generate within the body. Intestinal infections may be manifested by *in vivo* enterotoxin production or mucosal penetration. After mucosal penetration, the organisms multiply in the mucosa or pass into other tissues. See Fig. 1.

Diseases transmitted by foods can be placed into seven broad causative categories: (1) bacterial diseases, (2) viral and rickettsial diseases, (3) parasitic diseases, (4) fungal diseases, (5) plant toxicants and toxins, (6) toxic animals, and (7) poisonous chemicals, including radionuclides. Examples of principal diseases in these categories are given in Table 1. Although the listings of this table are helpful from the standpoint of classifying sources, the list tends to give equal weight to all diseases and does not convey seriousness, or frequency of occurrence. Several of the diseases occur rarely and, in some instances, they are highly regionalized.

In those countries with extensive communications networks, and in countries where there is advanced epidemiology and microbiological attention given to foodborne diseases, even one case of certain diseases can cause considerable excitement. Even one case can precipitate dramatic emphasis in the public press when recalls of certain processed foods may be involved. Worldwide reporting, however, is very poor. Even in some of the advanced countries, only a percentage of foodborne diseases is reported and thus many do not become part of formal statistics. For example, the Committee on Salmonella of the National Research Council (United States) estimates that about two million cases of salmonellosis occur in the country each year, but that only an average of about 20,000 isolations are made each year.

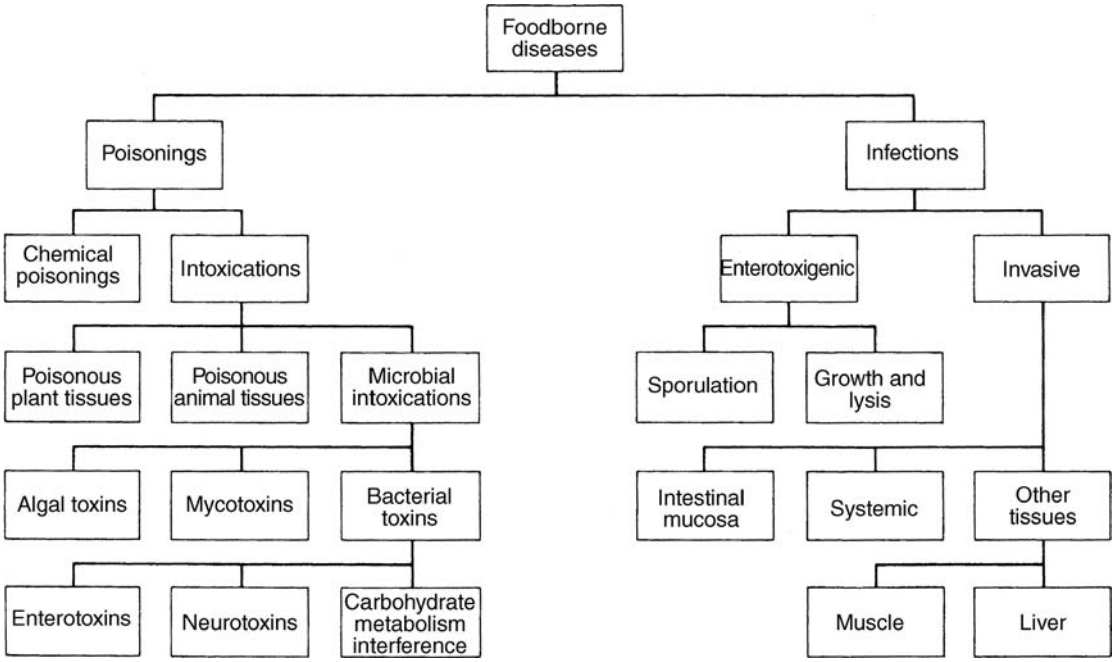

Fig. 1. Classification of foodborne diseases by basic sources and routes of development.

Epidemiology

Common terms used in the science of epidemiology (the study of the pattern of disease and the factors that cause the disease) include:

1. *Pattern* — of a disease is the composite of the relationships of time, place, and person within a group of cases. Time refers to onset of illness; place refers to residence, geography, and food sources; and persons refers to age, sex, occupation, ethnic group, social attributes, and food history of persons involved.
2. *Causal Factors* — are the agent, reservoir, vector, vehicle, host, and their interrelationships, as well as conditions that permit the agent to survive and/or multiply. These factors constitute the chain of infection for bacterial foodborne diseases, and the chain of actions in connection with other foodborne disease forms. In an epidemiologic investigation, the outbreak must be described in terms of its distribution and each of the causal factors must be determined.
3. *Epidemic* — the occurrence of a group of illnesses of similar nature in a community or region, clearly in excess of normal expectancy and derived from a common or propagated source. The minimum number of cases that indicates an epidemic will vary with the infectious agent, with the size and type of population exposed, with previous experience or lack of exposure to the diseases, and with the time and place of occurrence. Thus, an epidemic is relative to the usual frequency of the disease in the same area, among specified populations at the same season of the year. A single case of a communicable disease (as botulism or typhoid fever) long absent from a population, or a single case that is the first invasion by a disease (as *Vibrio parahaemolyticus* infection) not previously recognized in an area, is also to be considered epidemic. The word epidemic must be defined in contradistinction to the word endemic, which is the habitual presence of a disease or infectious agent within a given geographic area or the usual prevalence of a given disease within such an area. An obvious example of endemic and epidemic can be seen from the graph of pneumoniainfluenze deaths (used as example, although not foodborne) over a span of some 3 years. See Fig. 2.
4. *Epidemic curve* — is a graphical representation of cases according to the distribution of the time of onsets of cases. It is usually constructed as a histogram (see Fig. 3), but sometimes as a frequency polygon. In both types of graphs, the frequencies or number of cases is plotted on the ordinate axis and the time of onset of illness along the abscissa. The duration of each interval may be in hours, intervals of a few hours, etc. The interval selected depends upon the disease in question and the span of time over which cases occurred. A histogram represents each case or group of cases by a block in a unit of time. If more than one case occurs in a time interval, a block representing each additional case is stacked on the initial block. There are no vertical or horizontal spaces between blocks as in bar graphs.
5. *Common-source or point epidemic* — an epidemic that is spread by a vehicle, such as foods, milk, water, or fomites (inanimate objects — dishes, utensils, table tops, etc. that may be contaminated) shared by the victims. In a common-source outbreak, when many persons are exposed simultaneously, the relative uniformity of the incubation period for a specific disease results in a single cluster of cases in time. Cases occur rapidly after the first onset, reach a peak (*point*), and then decline. The duration of the epidemic will be within the range of the incubation period of the disease. The histogram of Fig. 3 indicates a common-source situation of a salmonellosis outbreak.
6. *Common-source, single-event epidemic* — is typified by onsets of cases that follow a single situation, as when a group of people eat the same contaminated food (*common source*) at the same place within a short period of time — as during a particular meal (*single event*). Distribution of cases will be stretched out in time when all persons have not eaten the contaminated food at the same time. Such a situation may be more accurately called a *common-source, multiple-event epidemic*.
7. *Propagated epidemic* — an epidemic that is transmitted from a human or animal reservoir by direct or indirect contact with a host. Reservoirs may be in the incubation period of a disease — they may be mild or missed cases, convalescents, or healthy *carriers*. For transmission to occur, the population must have enough susceptibles to give the infection a chance of spreading. As the disease spreads, those infected become immune, and the supply of susceptibles is depleted to a point at which spread tapers off and finally ceases. The rapidity with which contact-spread epidemics reach a peak and the extent of their duration depend upon infectivity of the agent, length of incubation period, initial proportion of susceptibles in the population, and degree of crowding and intimacy of contact. In zoonoses (animal parasites), the change in the proportion of susceptibles among animals and the distribution of the animals are factors that affect time distribution of cases. In vectorborne disease outbreaks, conditions that favor the development of a vector and the length of time that is required for the pathogens to develop in a vector will alter the time distribution of cases. A typical contact-spread epidemic is shown in Fig. 4. Data on 2 outbreaks of infectious hepatitis are shown in Fig. 5. One set of data defines a common-source outbreak in a city,

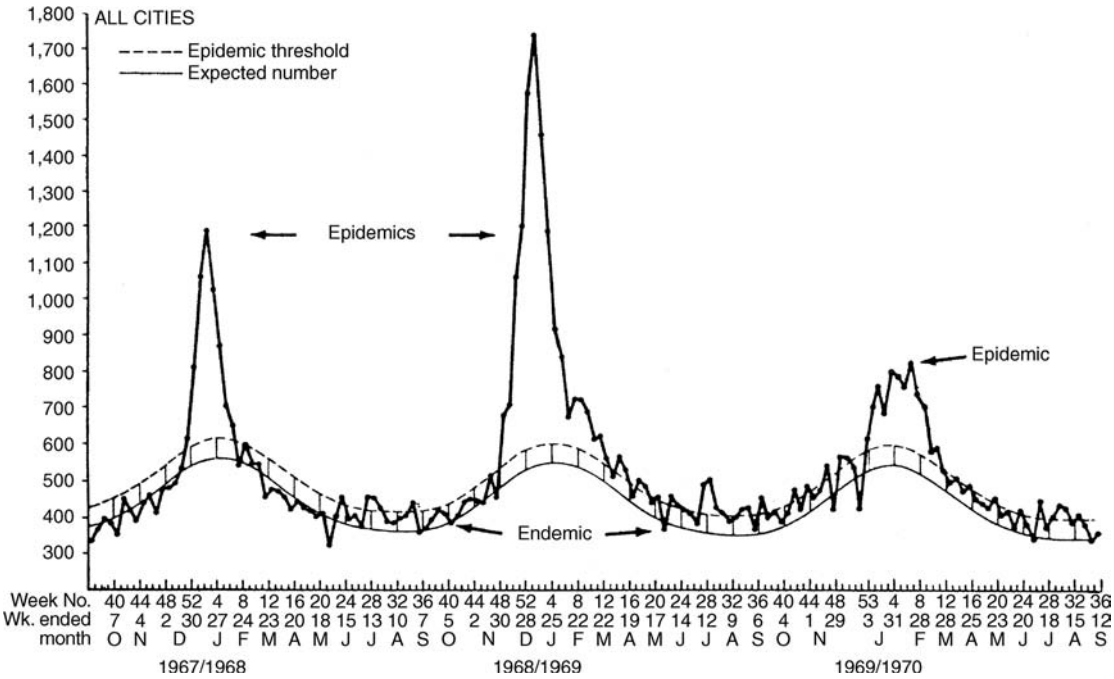

Fig. 2. Illustration of epidemic and endemic. The graph illustrates how an epidemic can be recognized. Epidemics are seen as a significant excess of cases (deaths in this example) over that which is expected on the basis of accumulated experience. The solid endemic line shows the seasonal pattern of the deaths, while the upper, broken line contains the upper level of variations below which 95% of expected observations should fall. When the observed numbers of deaths exceed the broken line for more than 2 successive weeks, an epidemic is indicated. Epidemics are observed during 3 successive years. From past experience of the occurrence of a disease in a community, epidemics can be forecasted. In this illustration, a forecast can be made that epidemics of death caused by pneumonia and influenza will occur again in winter and have higher peaks in the uneven numbered years. Generally, this technique can be used in connection with foodborne diseases, but involving a whole new set of causal factors for each disease being considered.

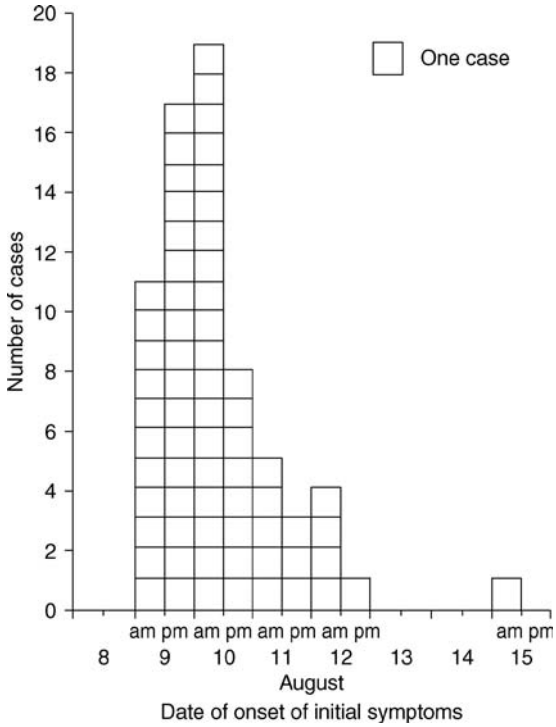

Fig. 3. Histogram (epidemic curve) of a common-source outbreak of salmonellosis.

the other set defines a propagated outbreak in the surrounding county in which the city is located.

8. *Incubation period* — the time between exposure of a susceptible person to an infection or toxic agent and appearance of the first sign or symptom of the disease. In foodborne outbreaks, it is the time between *ingestion* of contaminated or toxic food and the first symptom. The incubation period may be long or short, depending upon the peculiarities of each specific host-parasite relationship. The incubation period may also depend on the ease with which the infecting organism or toxin finds access to the tissue in which its primary multiplication or toxic reaction takes place. When a chemical that is an irritant to the gastrointestinal tract is ingested in sufficient quantity, vomiting follows in a short time, usually within an hour. Infectious hepatitis, which affects the liver, may have an incubation period of 15 to 30 days. The duration of the incubation period is an important characteristic of each disease. During an outbreak investigation, the incubation period cannot be determined until the responsible meal or time of ingestion of the incriminated food has been identified.
9. *Vector* — a means for transferring organisms from place to place. It is sometimes difficult to determine whether vectors are sources of contamination, or whether they pick up organisms from their environment. They do reflect the contamination of their environment and may transfer such contamination. If the environment of a plant, for example, is contaminated with a particular pathogen, finished products almost inevitably become contaminated.
10. *Outbreak* — in the United States, an outbreak of foodborne disease is a situation in which two or more people experience a similar illness, usually gastrointestinal, after ingestion of a common food and where epidemiologic analysis implicates the food as the source of the illness.

However, only one case of botulism or chemical poisoning constitutes an outbreak. Outbreaks are divided into two categories:

a. *Laboratory-confirmed outbreak* — in which laboratory evidence of a specific etiologic agent is obtained and specified criteria are met.
b. *Outbreak of undetermined etiology* — in which epidemiologic evidence implicates a food source, but adequate laboratory confirmation is not obtained. These outbreaks are further subdivided into four subgroups by incubation period of the illness:

Less than 1 hour — probable chemical causative
From 1 to 7 hours — probably *Staphylococcus* infection

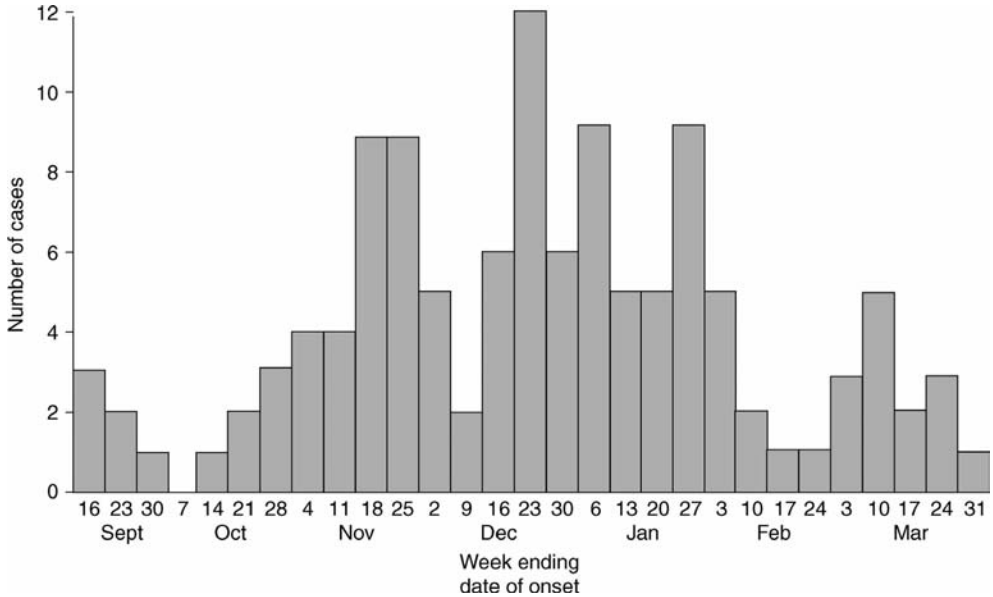

Fig. 4. Epidemic curve of a propagated outbreak of infectious hepatitis.

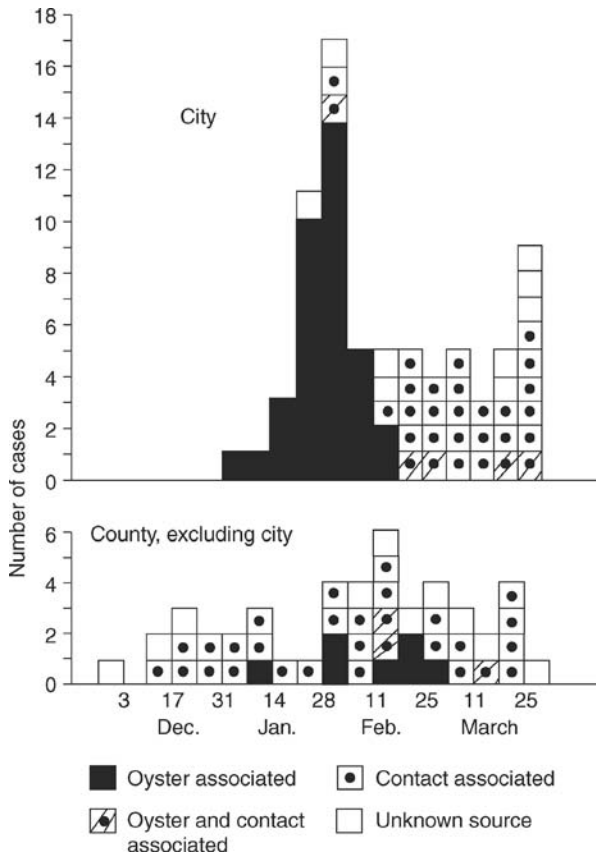

Fig. 5. Epidemic curve of a common-source outbreak with secondary infections and a propagated outbreak of infectious hepatitis.

From 8 to 14 hours — probable *Clostridium perfringens* infection
More than 14 hours — various other infectious agents.

Much of the information required by public health authorities in developing foodborne disease patterns stems from personal interviews with persons who have suffered (or are still suffering) the illness. Information also comes from people who appear to possess immediate knowledge of suspected places (household, restaurant, picnic, etc.), places where food was probably ingested and where it may have been contaminated prior to ingestion.

Important Foodborne Diseases

Salmonellosis. Salmonellosis is a foodborne disease that is caused by salmonellae (bacteria) other than *Salmonella typhi* and *Salmonella paratyphi*. Salmonellae are gram-negative, nonsporeforming (mostly) motile rod, aerobic, facultatively anaerobic microorganisms. There are over 1600 known serotypes, but only about 50 of these occur commonly. Species involved include *Salmonella choleraesuis* and *S. enteritidis*. Organisms possess O (somatic) and 2 phases of II (flagellar) antigens.

Incubation Period and Symptoms. Commonly, the incubation period ranges from 12 to 36 hours after food ingestion, although it may be as short as 5 and as long as 72 hours. Symptoms are one or more of the following: Diarrhea, abdominal pain, chills, fever, vomiting, dehydration, prostration, anorexia, headache, malaise. Duration of the disease may be several days. Enteritis or focal infection may also occur.

Most Likely Food Sources. Meats, poultry, eggs and their products. Other incriminating foods include: Coconut, cottonseed protein, chocolate candy, dry milk, smoked fish, and yeast.

Typical Sources and Reservoirs of Etiologic Agent. Feces of infected domestic or wild animals and humans.

Susceptibility and Carrier State. Most susceptible persons are infants, the elderly, and malnourished and those with concomitant diseases. However, the disease can affect persons of any age or state of health.

Preventive and Control Measures. Foods should be chilled rapidly in small quantities; foods should be cooked thoroughly. Egg products and milk must be pasteurized. Cross-contamination from raw to cooked foods must be avoided. Strict sanitary measures on the farm and in processing plants must be taken. Feed ingredients for livestock and poultry should be heat-treated. Very importantly, food and feeds must be protected from all excreta.

Other Salmonellae. Typhoid fever or enteric fever can be transmitted by food, *Salmonella typhi* is similar to other salmonellae, but is adapted to the human host. It possesses VI (capsular) antigens as well as O and H antigens. Water is also commonly implicated in outbreaks of typhus.

High-protein foods, raw salads, milk, shellfish are the usual categories of foods involved. These are largely foods that have been handled, and then eaten without further heat treatment. *Paratyphoid fever*, also sometimes called enteric fever, can be transmitted by foods. *Salmonella enteritidis* is also similar to other salmonellae, but is more or less adapted to the human host. This microorganism causes a blood stream infection. The disease is of a milder and shorter duration (1 to 3 weeks) than typhoid fever. Foods typically involved are milk, shellfish, raw salads, and eggs.

E.E. Telzak and a group of investigators with the New York State Department of Health reported infections due to *Salmonello* serotype *enteritidis* increased sixfold from 1976 to 1986. In 1987, the largest

TABLE 1. BROAD CATEGORIZATION OF FOODBORNE DISEASES

Bacterial Diseases

Salmonelloses
  Salmonellosis
  Enteric fever (typhoid fever)
Enteric fever (paratyphoid fever)
Staphylococcal Intoxication
Botulism
Clostridium perfringens (C. welchii)
  Type A Disease
  Type C-Enteritis Necroticans
Bacillus cereus
  Gastroenteritis
Vibrio parahacmolyticus
  Infection
Arizona hinshawli
  Arizona infection
Pseudomonas cocovenenans (toxins)
  Bongkrek poisoning
Proteus spp. (histaminelike substances)
  Scombroid poisoning (Scombrotoxism; Saurine poisoning; Fish poisoning)

Note: Bacterial diseases usually transmitted by other means, but sometimes foodborne, include: Shigellosis; enteropathogenic *Escherichia coli* infection; beta hemolytic streptococcal infections, such as scarlet fever, septic sore throat; yersiniosis (*Yersinia enterocolitica* infection or pseudotuberculosis); cholera; brucellosis; tuberculosis; diphtheria; tularemia; anthrax; Haverhill fever.

Bacterial diseases in which proof of transmission by foods is inconclusive include: Enterococcal infection; Klebsiella food infection; enterobacter infection; *Pseudomonas aeruginosa* infection; *Bacillus subtilis* infection; listeriosis, among others.

Viral and Rickettsial Diseases

Hepatitis A (Infectious hepatitis)
Poliomyelitis
Bolivian hemorrhagic fever
Russian spring-summer encephalitis (Diphasic milk fever)

Parasitic Diseases (Helminthic)

Trichinosis
Taeniasis

Note: Other parasitic diseases always or usually transmitted by foods, but less commonly encountered, include: cysticercosis; diphyllobothriasis; spargnosis; angiostrongyliasis; anisakiasis; fasciolopsiasis; echinostomiasis; heterophyid infection; opisthorchiasis; metagonimiasis; fascioliasis; paragonimiasis; dicrocoeliosis; hymenolepiasis diminuta; gnathostomiasis; intestinal myiasis.

Parasitic diseases which are usually transmitted by other means, but which may be foodborne, include: Amebiasis (amebic dysentery); ascariasis; trichuriasis; *Capillaria hepatica* infection; echinococcoses hydatidosis; alveolor hydatid disease; balantidiasis (balantidal dysentery); giardiasis; coccidiosis (Isospora infection); dientamoeba infection; toxoplasmosis; sarcosporidiosis.

Fungal Diseases

  Mycotoxicoses reported in humans
  Alimentary toxic aleukia (ATA)
  Urov diseases (Kaschin-Beck disease)
  "Drunken-bread" poisoning
  Akakabi-byo (Red mold disease)
  Ergotism (Saint Anthony's fire)
  Epidemic polyurea
  Toxic moldy rice disease
  uco-mycotoxic disease
  Aflatoxicosis

Note: Mycotoxicoses of animals that may also potentially affect humans include: Strachybotryotoxicosis; ochratoxicosis; aspergillus toxicosis; moldy corn toxicosis; facial eczema.

Mushroom-associated diseases
  Mushroom poisoning-Cell destruction
  Mushroom poisoning-Neurological effects
  Mushroom poisoning-Enteritis type
  Mushroom-alcohol intolerance
Mycotic infections
  Phycomycosis

Plant Toxicant and Toxin Diseases

Alkaloids
  Jimson weed and nightshade poisoning; senecio poisoning; hemlock poisoning; epidemic dropsy; manchineel poisoning; laburnum poisoning; solanine poisoning; green hellebore poisoning; delphinium and monkshood poisoning; yew poisoning; daffodil bulb poisoning; jessamine poisoning; colchicine poisoning; nicotine poisoning.
Glycosides
  Cyanide poisoning; goiter; baneberry poisoning; buckeye poisoning; oleander, lily-of-the-valley, and black hellebore poisoning; pokeweed, corn cockle, and finger cherry poisoning; tung nut poisoning.
Toxalbumins
  Castor bean and jequirity poisoning; favism.
Resins
  Water hemlock poisoning; mountain laurel poisoning
Other Toxicants, Toxins, and Allergens
  Milk sickness; cocculus poisoning; ackee poisoning; lathyrism; oxalate poisoning; mistletoe poisoning; nutmeg poisoning; *Leucaena glauca* poisoning; djenkol poisoning; carotenemia; esophageal cancer.

Note: There are many other plants and substances that can cause toxic and allergenic illness, including common house and garden plants.

Toxic Animals (Disease Sources)

Fish
  Ciguatera poisoning; moray eel poisoning; file fish poisoning; tetraodon or puffer fish poisoning; scombroid poisoning; clupeoid poisoning; elastobranch and chonrichytes poisoning; chimaeroid poisoning; cyclostome poisoning; gempylid poisoning; hallucinogenic fish poisoning; ichthyohepatoxism; freshwater fish poisoning; Haff or Yuksov disease; Minamata disease.
Shellfish
  Paralytic shellfish poisoning; oyster poisoning; callistin shellfish poisoning; abalone poisoning; whelk poisoning.
Other Animals
  Cephalopod poisoning; sea urchin poisoning; sea anemone poisoning; sea cucumber poisoning; horseshoe crab poisoning (mimi poisoning); turtle poisoning; hypervitaminosis A; porpoise poisoning; toxic quail poisoning.

Poisonous Chemicals (Disease Sources)

Metallic Containers
  Zinc, cadmium, antimony, copper, lead, tin poisoning.
Intentional Additives
  Nitrite poisoning; niacin poisoning; triorthocresyl phosphate poisoning; diphenylhydatoin intoxication; Oriental (Chinese) restaurant syndrome (excessive monosodium glutamate); potassium bromate poisoning; beer drinkers' cardiomyopathy (cobalt acetate); margarine disease; phenolphthalein poisoning.
Incidental and Accidental Food Additives
  Organic phosphorus poisonings (from insecticides); chlorinated hydrocarbon poisoning (from insecticides); carbamate poisoning (from insecticides); fluoride poisoning (from rodenticides); sodium monofluoroacetate poisoning (from rodenticides); thallium poisoning (from rodenticides); warfarin poisoning (from rodenticides); arsenic poisoning (from insecticides and herbicides); phosphide poisoning (from rodenticides and matches); barium poisoning (from rodenticides); nicotine sulfate poisoning (from insecticides and tobacco products); alkyl-mercury poisoning (from fungicides) epoxy resin poisoning (from contaminated grains); chromium poisoning (from vending machines); calcium chloride poisoning (contaminated popsicles); cyanide poisoning (from fumigants); lye poisoning (from household chemicals); methyl alcohol poisoning (paint solvents and bootleg whiskey); chronic cadmium poisoning (Itai Itai or ouch ouch disease (mining wastes deposited in rice paddies)); yusho (rice oil disease-from salad oil); selenium poisoning (home-grown foods with high concentrations of selenium, such as monkey coconut).
Allergens or Enzyme Deficiencies
  Gastrointestinal food allergies
    Allergens react with antibody and form histamine or histamine-like substances; (Depends upon sensitivity of individual-not general)
    Milk (protein constituents)
    Milk products
    Egg (whites)
    Cereals (wheat, buckwheat, corn, rice, rye, oats)
    Fish and seafoods

(*continued*)

TABLE 1. (*Continued*)

Meats
Nuts
Spices
Vegetables (celery, string beans, lima beans, tomatoes)
Fruits (oranges, strawberries, bananas, lemons, watermelon)
Preservatives
Disaccharide intolerance
Lactose, sucrose, or isomaltose; (High incidence in blacks and orientals)
Milk and other foods containing disaccharides
Food-drug combinations
Amine poisoning
Tyramine in cheese can be degraded to p-hydroxyphenylacetic acid by monoamine oxidase inhibitors in certain tranquilizers, causing hypertensive attacks.
Mushroom-alcohol intolerance (Specifically inky cap mushroom)
Listed under fungal diseases. Disulfiramlike (antabuse) constituents of mushroom interfere with normal metabolism of alcohol. Attacks can occur even if alcohol is consumed 48 hours after eating mushrooms.
Radionuclides
Food contamination may arise from fallout, reactor plant accidents, radioactive wastes, naturally occurring radioactive substances.
$Strontium^{89}$ (milk)
$Strontium^{90}$ (green leafy vegetables, milk, milk products)
$Iodine^{131}$ (milk)
$Cesium^{137}$ (green leafy vegetables, milk, milk products, meat, shellfish, fish)
$Phosphorus^{32}$ (green leafy vegetables)
$Barium^{140}$ (milk)
$Ruthenium^{106}$ (laverbread made from seaweed components)

Source: Bryan

outbreak of record in the United States occurred, in which 404 of the 965 patients (42 percent) at one hospital were affected, and 9 patients died. An epidemiological study implicated raw eggs, and the ovary of a hen from the farm corporation that supplied the implicated eggs. This outbreak was distinguished by its substantial morbidity and mortality. As a result, the New York State Department of Health issued recommendations to all health care facilities in New York State to eliminate raw or undercooked eggs from the diets of persons who are institutionalized. Further measures included a survey for the presence of *S. enteritidis* in the flocks of hens raised for breeding and the production of table eggs.

Staphylococcal Intoxication. Also termed *staphyloenterotoxicosis*, staphylococcal intoxication is caused by *Staphylococcus aureus*. The etiologic agent is enterotoxin A, B, C, D, E, or F of *S. aureus*. This microorganism is gram-positive, nonsporeforming, nonmotile cocci occurring in irregular grapelike groupings. Other properties of the microorganism include — aerobic; facultatively anaerobic; coagulase-positive; ferments mannitol; grows well in 10% salt media; produces lipase and hemolysin; often produces orange or yellow pigments and heat-stable enterotoxin; resistant to antibiotics.

Incubation Period and Symptoms. Commonly, the incubation period ranges from 2 to 4 hours, although it may be as short as 1 and as long as 7 hours after food ingestion. Symptoms are one or more of the following: Sudden onset of nausea, salivation, vomiting, retching; diarrhea; abdominal cramps; dehydration; sweating; weakness; prostration. Fever usually does not occur. Disease is usually of a short duration of about 1 or 2 days.

Most Likely Food Sources. Cooked ham; meat products; poultry and dressings; sauces and gravies; cream-filled pastry; potato, ham, poultry, and fish salads; milk; cheese; hollandaise sauce; bread pudding; and many high-protein leftover foods.

Typical Sources and Reservoirs of Etiologic Agent. Nose and throat discharges; hands and skin, particularly from infected cuts, wounds, and burns; boils, pimples, acne; feces. The anterior nares of humans are the primary reservoir. In cows and ewes, it is the mastitic udder. In poultry, the arthritic and bruised tissue. In most cases, where the disease develops, it will be from food that has been contaminated after cooking or processing.

Preventive and Control Measures. Very similar to the general measures described under "Salmonellosis." In particular, ill persons suffering colds, infected cuts, and diarrhea, should not be permitted to be in the food-preparation area. Thorough cooking, reheating, and pasteurization destroy the microorganisms, but unfortunately, they do not destroy any toxin that may be present. Wherever possible, foods should be prepared on the same day they are served. As previously mentioned, freezing does not fully control the microorganism, with outbreaks occurring from time to time after thawing frozen cream-filled pastries.

Treatment of the illness consists of fluid and electrolyte repletion. Death rarely occurs, except in infants or in elderly or debilitated persons.

In a scholarly report, researchers P. Marrack and J. Kappler (University of Colorado) report on the poorly understood mechanisms of the staphylococcal enterotoxins and a group of related proteins made by *Streptococci* in causing food poisoning and shock in man and animals. See reference listed.

As reported by P. Hardt-English and co-researchers, several outbreaks of staphylococcal food poisoning occurred in the United States in 1989 as a result of people consuming canned mushrooms imported from China. At least four separate incidents were documented with more than 100 people becoming ill. Eight canneries from five different provinces in China showed the presence of staphylococcal enterotoxin in their products. This study highlighted the importance of the HACCP food regulation procedures, which are described later in this article.

Botulism. Botulism is a foodborne disease that is caused by the toxins A, B, E, or F of *Clostridium botulinum*. Toxins C and D cause botulism in animals. Type G, found relatively recently, has not, to date, caused any human cases of the illness. The microorganism is a gram-positive, sporeforming, motile rod. Neurotoxins are formed which interfere with acetylcholine at peripheral nerve endings. The spores are among the most heat-resistant of those found in connection with foodborne diseases. The toxins are heat labile. Fatalities have occurred in cases in which victims have tasted only a very small amount of the toxin-containing food. Despite the potent aspects of botulinus toxin, improvements in respiratory care have helped to reduce the mortality in cases of botulism from 60 to 20%. There is also available a trivalent antitoxin, which when administered promptly, is very effective in most cases in modifying the course of the disease. Cases of botulism also can result from infection of wounds by *C. botulinum*, but the great majority of cases result from ingestion of contaminated food.

Cases and outbreaks of botulism occur in many parts of the world and in all regions of the United States, but the disease is most frequently found in the western United States, notably in Alaska, California, Colorado, Oregon, and Washington. Cases in Alaska, in several instances, have been attributed to toxins released: from raw fish that has been aged in plastic bags, from seal meat that has been stored in oil, and from smoked salmon that has been wrapped in seal skins.

Incubation Period and Symptoms. Commonly, the incubation period ranges from 12 hours to 36 hours after food ingestion, although it may be as short as 2 hours and as long as 6 days. Symptoms are one or more of the following: Nausea, vomiting, abdominal pain, and diarrhea — signs that may appear early. Headache, vertigo or dizziness, lassitude, double vision, disphagia, dyspnea, ataxia, dry mouth, weakness, constipation, respiratory distress, respiratory paralysis may develop. Partial paralysis may persist for 6 to 8 months. Sensorium is usually clear. When the disease is fatal, death usually occurs within 3 to 10 days.

Of paramount importance is the maintenance of ventilation of the patient. The treating physicians will check for impending respiratory failure by taking serial measurements of vital capacity; actual respiratory failure can be recognized by changes in arterial blood gas levels. As lifesaving interventions, endotracheal intubation, eventual tracheostomy, and use of mechanical ventilators are available. The use of guanidine to increase acetylcholine release from nerve terminals remains controversial.

Infant Botulism. Botulism in infants was first recognized in 1976, and it has appeared with surprising frequency since that time. Some authorities in the past have suggested that infant botulism may be incriminated in connection with some cases of *sudden infant death*.

Some authorities believe that infant botulism may not be caused by ingestion of toxin, but rather by the colonization of the intestine by *C. botulinum*, followed by absorption of the toxin. Honey has been implicated in about one-third of the cases and, consequently, some physicians recommend that honey not be fed to infants under 1 year of age. Onset

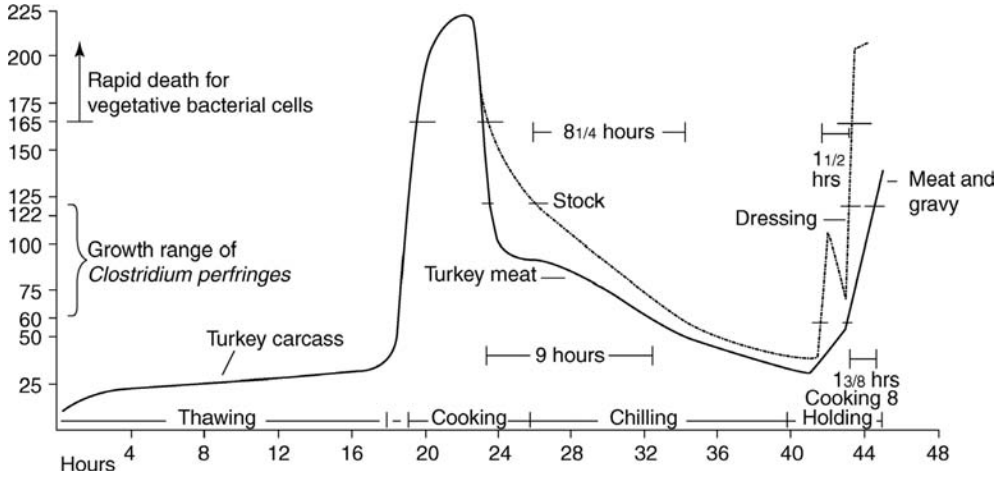

Fig. 6. Time-temperature relationship of a turkey preparation in a school lunch kitchen. In this case, *C. perfringens* could multiply during the 7 to 8 hours in which the meat and stock were in a refrigerator. The organisms present in the meat and gravy would have survived the reheating process. This particular chart was constructed as part of a time-temperature study of the thawing, cooking, chilling, and reheating practices that were used for turkeys which were implicated in a foodborne disease outbreak.

of the disease (between 5 and 20 weeks) is characterized by constipation, followed by cranial neuropathy which produces muscle weakness. Infants displaying such symptoms have sometimes been described as "floppy." Sudden death may result from hypoventilation and apnea.

Twenty-four-hour consultative and laboratory services are maintained by the Centers for Disease Control (CDC) in Atlanta, Georgia, from which polyvalent and monovalent botulinal antitoxins also are obtainable.

Most Likely Food Sources. The sources particularly pertinent to Alaska have been described. Foods generally implicated are improperly canned, low-acid foods (green beans, corn [maize], beets, asparagus, chili peppers, mushrooms, spinach, figs, olives, tuna). Smoked fish and fermented foods also have been implicated.

Preventive and Control Measures. Cans should be heated at high temperatures under pressure for sufficient time. Home-canned foods should be cooked thoroughly, by boiling and stirring for a considerable time. In addition to adequate refrigeration, addition of acidic substances and salt can be helpful. The availability of antitoxins has been mentioned.

Therapeutic Uses of Botulinum Toxin. It is interesting to note that botulism was recognized in the 18th century, but the observation that a toxin produced by an anaerobic organism might be responsible for food poisoning was not made until 1897. As pointed out by J. Jankovic (Baylor College of Medicine) and M.F. Brin (Columbia University College of Physicians and Surgeons), "Although seven immunologically distinct toxins have been identified, only types A, B, and E have been linked to cases of botulism in humans. Botulinum toxin type A (referred to as botulinum toxin) is one of the most lethal biologic toxins. It has been found to be of therapeutic value in the treatment of a variety of neurologic and ophthalmologic disorders." The U.S. Food and Drug Administration approved in 1991 the use of botulinum toxin as a therapeutic agent in patients with strabismus, blepharospasm, and other facial nerve disorders, including hemifacial spasm.

Clostridium Perfringens. During sporulation in the gut, *Clostridium perfringens* (*welchii*) type A microorganisms release a proteinous enterotoxin. However, large numbers of vegetative cells must be ingested. This microorganism is a gram-positive, sporeforming, nonmotile, encapsulated short rod. It is anaerobic and produces lecithinase. There are both heat-resistant (some survive boiling for 1 to 5 hours) and heat-sensitive spores. Heat shock encourages spores to germinate. There are approximately 82 known serotypes.

Incubation Period and Symptoms. Commonly, the incubation period ranges from 8 to 24 hours, with a median of 12 hours. Symptoms include one or more of the following: Acute abdominal pain, diarrhea, occasional dehydration and prostration. Nausea, vomiting, fever, and chills are rare. The disease is of short duration (1 day or less).

Although *C. perfringens* food poisoning is essentially confined to incidences of gastroenteritis, the microorganism when present in severe body wounds can have serious consequences. For infection to occur, a lowered oxidation-reduction potential, which allows spore germination and bacterial multiplication, is required. Tissue necrosis, impairment of blood supply, and introduction of foreign bodies provide such an environment. Major determinants of pathogenicity for invasive clostridia are their potent exotoxins. Once bacterial multiplication and toxin production occur at a site of injury, rapid invasion and destruction of healthy tissue ensue.

Most Likely Food Sources. Cooked meat and poultry that has remained at room temperature for several hours or slowly cooled. See Fig. 6. Gravy, stew, and meat pies. Illness from *Clostridum perfringens* in meat products is a major concern in the food industry. Long-time, low-temperature (LTLT) cookery for beef or other meat in the processing industry, food service establishments, and the home creates potential for substantial growth of *C. perfringens* during cooking.

Preventive and Control Measures. Foods should be chilled rapidly in small quantities. Excellent personal hygiene by all personnel (including household) should be practiced. Hot foods should be held at 140 °F (60 °C) or higher. Meats marketed as cured meats should be processed under rigid restrictions. Sewage should be disposed in a sanitary manner. Thorough cooking will destroy vegetative cells, but not the heat-resistant spores. When reheating leftover foods, they should reach a minimum temperature of 165 °F (74 °C).

Clostridium perfringens Type C. This is a gram-positive, sporeforming, nonmotile rod, anaerobic microorganism. This microorganism was formerly called type F. Lecithinase and necrotoxin are produced. The strains differ in minor antigens. The incubation period ranges from 6 hours to 6 days, but is usually about 24 hours. Symptoms include diarrhea, prolonged abdominal pain, gangrene of small intestine, shock, toxemia. Case fatality rate of this type is about 40%.

Most likely food sources include pork, other meats, and fish. Preventive measures include eating a balanced diet. Foods should be chilled rapidly in small quantities. As with type A, thorough cooking will destroy vegetative cells, but not the heat-resistant spores. Leftovers should be reheated to 160 °F (71 °C) and hot foods should be held at temperatures greater than 140 °F (60 °C).

Type *C Clostridium perfringens* disease is sometimes called *enteritis necroticans* or *Pig-Bel*.

Bacillus Cereus Gastroenteritis. The etiologic agent of this foodborne disease is exoenterotoxin of *B. cereus*. The microorganism is a gram-positive, sporeforming, motile rod, frequently in the form of chains. Lecithinase is produced.

Incubation Period and Symptoms. Commonly, the incubation period ranges from 8 to 16 hours, but may be as short as 1.5 to 5 hours. Symptoms include one or more of the following: Nausea, abdominal cramps, watery diarrhea, some vomiting. Where there is a short incubation period, nausea and vomiting predominate. In many ways, the disease

is similar to staphylococcal intoxication. The illness is usually of short duration (1 day or less).

Most Likely Food Sources. Custards, cereal products, puddings, sauces, meat loaf, fried rice. Preventive and control measures are essentially the same as those described for *Clostridium perfringens* type A illness.

Vibrio Parahaemolyticus Infection. This foodborne illness is produced by *Vibrio parahaemolyticus* microorganisms. The microorganism is gram-negative, straight or curved motile rod and is aerobic and facultatively anaerobic. The microorganism resists 7%, but not 10% sodium chloride media. Possesses O, K, and H antigens.

Incubation Period and Symptoms. Most commonly, the incubation period is 12 hours, although it may be as short as 2 hours and as long as 48 hours. Symptoms include one or more of the following: Abdominal pain, diarrhea (watery stools containing blood and mucus), usually nausea and vomiting, mild fever, chills, headache, prostration. Recovery usually occurs within 2 to 5 days.

Most Likely Food Sources. Raw foods of marine origin. Saltwater fish, shellfish, crustaceans, and various fish products. Cucumbers and other salty foods have been implicated. Reservoirs of the microorganism are sea water and marine life. A large percentage of the illnesses have been reported in Japan, particularly in warmer months. Occurrence is less in the United States and other parts of the world.

Preventive and Control Measures. Foods must be cooked thoroughly. Chilling should be rapid and in small quantities. Cross contamination from saltwater fish must be avoided. Seawater should not be used for rinsing foods to be eaten raw, or for cleaning.

Shigellosis or Bacillary Dysentery. This disease is usually transmitted by interpersonal spread. However, common-source foodborne out-breaks are reported from time to time. The etiologic agents include *Shigella sonnei, S. flexneri, S. dysenteriae,* and *S. boydii*. Shigellae are host specific to humans and thus food substances can be contaminated only by contact with the feces of infected humans. Foods most likely to be contaminated include moist, mixed foods; milk; beans; potato, tuna, shrimp, turkey, and macaroni salads; apple cider; and poi. The incubation period ranges from 1 to 7 days, but usually is less than 4 days. Symptoms are quite variable, ranging from mild to severe, involving abdominal cramps, fever, chills, diarrhea, headache, tenesmus, lassitude, prostration, nausea, and dehydration.

Yersiniosis. This sometimes foodborne disease, also known as *pseudo-tuberculosis,* is caused by *Yersinia pseudo-tuberculosis,* or *Y. enterocolitica*, which are gram-negative, motile rods. Coccoid forms predominate in young cultures. Microorganisms are aerobic, facultatively anaerobic. The incubation period is from 24 to 36 hours or longer. Likely food sources include pork and other meats, raw milk, unpasteurized ingredients of milk products, such as chocolate, and any other contaminated raw or leftover food. Sources and reservoirs include the urine and feces of infected animals, frequently rodents, dogs, and pigs. The microorganisms also are found in soil, dust, and water. Control measures include cooking foods thoroughly and protecting food supplies from contamination by rodents.

Relatively uncommon, yersiniosis occurred in outbreak proportions in central New York (near Utica) in the late 1970s. The ailment affected 218 children and, because the disease mimics appendicitis, 13 needless appendectomies were performed. The disease was first traced to school eating facilities and finally narrowed down to the milk. Upon investigation, it was found that unpasteurized chocolate flavoring had been added to the milk after the milk per se had been pasteurized. Prior to this incident, only about 100 cases had previously been recorded. The first epidemic occurred in the United States in 1973 among four rural North Carolina families, living with poor sanitary facilities. Contaminated milk caused that outbreak.

Foodborne Viral and Rickettsial Diseases. Epidemiological evidence has confirmed the foodborne transmission of several viral diseases, including hepatitis A, poliomyelitis, Bolivian hemorrhagic fever, Russian spring-summer encephalitis, and Q fever. There are also several viral diseases that could possibly be transmitted by foods, but where solid proof is lacking. These include summer grippe (Coxsackie group A viruses), epidemic myalgia (pleurodynia), echo virus infections (enteric cytopathogenic human orphan viruses), hepatitis B (serum hepatitis), and nonbacterial gastroenteritis (possibly caused by the Norwalk agent). See also **Coxsackie Virus**; and **Norwalk Virus**.

Hepatitis A (Infectious Hepatitis). Caused by hepatitis virus A, this illness has an incubation period of from 10 to 50 days, but is about 30 days on the average. This is a systemic infection characterized by constitutional and gastrointestinal manifestations and by injury to the liver. Fever, malaise, lassitude, anorexia, nausea, abdominal discomfort, bile in urine, and jaundice all are symptoms. Severity usually increases with the age of the patient. Duration of the illness ranges from a few weeks to several months.

Suspect food sources include shellfish, milk, orange juice, potato salad, frozen strawberries, glazed doughnuts, whipped cream cakes, and a variety of sandwiches. Sources and reservoirs of the virus are the feces, urine, and blood of infected human cases and persons incubating or convalescing from the disease. Although foodborne, the main routes of transmission are person-to-person contact and drinking water. Good preventive measures include cooking foods thoroughly, to inactive the virus, and to avoid pollution of shellfish growing areas. Drinking water must be fully treated, including chlorination. Known cases of hepatitis A should be isolated for 7 to 10 days after jaundice, and all equipment used for parenteral injections should be thoroughly sterilized. Give gamma globulin to contacts.

Charting of hepatitis outbreaks are given earlier in this entry. See Fig. 4.

General Study of Viruses Associated with Food Supply. In 1977, Kostenbader and Cliver (Food Research Institute, Department of Food Microbiology and Toxicology — Department of Bacteriology and World Health Organization Collaborating Centre on Food Virology — University of Wisconsin, Madison, Wisconsin) conducted a study on the association of viruses with food processing and distribution, with emphasis on the food processing plant. Seven plants were selected for examination and the details are well reported in the listed reference. The researchers concluded, in part: No viruses were found in plants processing vegetable products, nor in three of those working with animal products. Incoming swine at one slaughter plant frequently harbored viruses in their intestines; these were apparently not infectious for humans and were not seen in the final product. An agent too elusive to be characterized was found in frozen ground beef patties from another plant; this agent did not appear to be infectious for humans. A further survey of sanitary sewers at nine plants showed that the incidence of intestinal virus infections in processing personnel was below detectable limits. No virus was detected in 60 samples (2 of each of 6 foods from 5 markets). Research for virus-food connections continues.

Toxic Fishes and Shellfish. These diseases include: scombroid poisoning, ciguatera poisoning, moray eel poisoning, ichthyohemotoxism (fish serum toxin), file fish poisoning, tetradon or puffer fish poisoning, clupeoid poisoning, elasmobranch and chondrichthyes poisoning, chimaeroid poisoning, cyclostome poisoning, gempylid poisoning, hallucinogenic fish poisoning, ichthyohepatoxism, freshwater fish poisoning, Haff or Yuksov disease, Minamata disease, paralytic shellfish poisoning, oyster poisoning, callistin shellfish poisoning, abalone poisoning, whelk poisoning, horseshoe crab poisoning, turtle poisoning, hypervitaminosis A, porpoise poisoning, and toxic quail poisoning. It will be noted from the names of these diseases that they are, in many instances, quite specific to a given order or species of animal. Also, that the maritime animals predominate. A few of these diseases are described here in some detail.

Ciguatera Poisoning (Ichthyosarco Toxism). The exact nature of the etiologic agent of this foodborne disease (one aspect of *seafood poisoning*) has not been definitely established. Some authorities believe that the toxin is accumulated through the food chain in bottom-dwelling large fish (barracuda, red snapper, amberjack, and grouper). These fish are usually caught near ocean reefs, predominantly in the region between latitudes 35°N and 35°S. Eleven orders, 57 families and over 400 species of marine animals have been incriminated in connection with this poisoning. Some authorities believe that any marine fish may be potential transvector of ciguatoxin. The poison is concentrated in fish gonads, liver, intestines, and muscles. Good prevention is to avoid eating these parts of the suspect fishes. Eating of unusually large reef fishes should be avoided. There is no reliable method of detecting poisonous fishes by their appearance. Neither frying, baking, boiling, broiling, stewing, steaming, drying, salting, nor any other ordinary cooking method, destroys ciguatoxin.

The first signs of poisoning are usually observed within 3 to 5 hours after food ingestion, but may be as long as 24 hours. Symptoms begin with nausea, vomiting, abdominal cramps, and diarrhea. Paresthesias involving the lips, tongue, mouth, pharynx, and extremities are a prominent feature of the disease. Other symptoms include myalgias, arthralgias, blurred vision,

photophobia, transient blindness, and cranial nerve palsies. In severe cases, bradycardia, hypotension, and respiratory paralysis appear early.

Symptoms usually subside after a few days, but weakness and sensory disturbances can persist for quite some time in rare cases. Fatalities are rare. There is no specific treatment for the disease. Where respiratory paralysis develops, mechanical ventilation may be indicated.

Scombroid Poisoning (Scombrotoxism; Saurine poisoning). This foodborne disease comprises another aspect of seafood poisoning. The etiologic agents are histaminelike substances and possibly saurine (*Proteus* spp.). Histidine in flesh is broken down by action of *Proteus* spp. or other organisms. It is thermostable and can withstand boiling for at least 1 hour. Histamine is a capillary dilator. Symptoms of the poisoning are evident from a few minutes after ingestion to about 1 hour. There is intense headache, dizziness, nausea, vomiting, metallic or peppery taste, diarrhea, facial swelling and flushing, epigastric pain, throbbing of carotid and temporal vessels, rapid and weak pulse, burning of throat, thirst, difficulty in swallowing, edema, and itching of skin. Although this is an illness of great discomfort, recovery usually occurs within 12 hours.

Likely sources of this poison are scombroid fishes, such as tuna, bonito, mackerel, and skipjack. Good prevention requires refrigeration of fish immediately after they are killed. The fish should be consumed promptly, if not immediately refrigerated.

Upon noting first symptoms, and if vomiting and diarrhea have not already occurred, ipecac and cathartics can be used initially. Antihistamines and bronchodilators may provide symptomatic relief. Of several hundred reported cases of scombroid poisoning, no fatalities have occurred.

In one year, scombroid fish poisoning occurred in 232 persons who had eaten from either of two lots of commercially canned tuna. Cases occurred in four states (United States), with no reported hospitalizations or deaths. Patients became ill about 45 minutes after eating the fish. Symptoms lasted about 8 hours. Contaminated fish contained histamine levels of 68 to 280 milligrams/100 grams of fish muscle. This was the first reported outbreak associated with a commercially canned fish product. Numerous outbreaks have occurred in Japan where fresh fish is a substantial part of the diet. One Japanese report described 14 outbreaks involving 1215 persons within a 4-year period. Some cases of so-called "tuna fish allergy" probably represent scombroid fish poisoning.

Paralytic Shellfish Poisoning (Dinoflagellate Poisoning). This foodborne disease is yet another aspect of seafood poisoning. The etiologic agent is saxitoxin, a neurotoxin that blocks neuromuscular junctions. It is an alkaloid and relatively heat-stable. it is water-soluble. During red tides, cell counts of plankton blooms may reach from 20 to 40 million per milliliter. Onset of the illness usually occurs within less than 1 hour after food ingestion. Symptoms include tingling or burning and numbness around lips, finger tips and extremities. In severe cases, muscle paralysis develops and leads to dysphonia, dysphagia, and ventilatory impairment. Death caused by respiratory paralysis may occur within the first 12 hours.

The gastrointestinal tract must be emptied of any unabsorbed toxin, with care taken to avoid aspiration. Measures designed to support the cardiovascular and respiratory system should be commenced quickly. Use of a mechanical ventilator may be required.

Oyster Poisoning (Asari or Venerupin Poisoning). The etiologic agent is venerupin (asaritoxin), which is a heat-stable toxin. Toxicity remains even after 1 hour of boiling. The toxin is organotropic, affecting mainly the liver. Symptoms may be evident within 6 hours, or as long as 7 days after food ingestion. However, onset of the illness usually is apparent within 24 to 48 hours. Symptoms include anorexia, abdominal pain, nausea, vomiting constipation, headache, malaise, nervousness, halitosis, bleeding of mucus membrane of nose, mouth, and gums, delirium. There is no paralysis. Case fatality rate is as high as 33%.

Food sources are oysters and clams (asari), including *Crassostrea gigae*, *Dosinea japonica*, and *Tapes semidecussata*. Prevention is essentially control of shellfish harvesting practices.

Abalone Poisoning. The etiologic agent is described as a photodynamic principle that causes photosensitization. The substance is stable to boiling, freezing, and salting. Timing of onset of disease is dependent upon exposure to sunlight. Where accompanied by exposure to sunlight, onset is sudden, with burning and stinging sensation over entire body, prickling sensation, itching, erythema, edema, skin ulceration on parts of body exposed to light. The food source is the Japanese abalone (*Haliotis discus*, or *H. sieboldi*). Best prevention is to make certain that there are no viscera of abalone in food served. It has been suggested that a seaweed of the genus Desmarestia may be the source of the toxin.

Tetraodon or Puffer Fish Poisoning. There are about 90 toxic species of puffer fish (fugu, blowfish, globefish, porcupine fish, molas, burrfish, balloonfish, and toadfish). The etiologic agent is tetrodotoxin (tetraodontoxin). This is a neurotoxin (paralysis of central nervous system and peripheral nerves). The toxin is stable to boiling except in alkaline solution. Toxin is water-soluble. The toxin mainly attacks nerve endings by blocking movements of all monovalent cations. Onset of illness usually occurs within 10 to 45 minutes after ingestion, although it may be delayed up to 3 hours. Symptoms include: tingling or prickly sensation of fingers and toes, malaise, dizziness, pallor, numbness of lips, tongue, extremities; ataxia, nausea, vomiting, diarrhea, epigastric pain, dryness of skin, subcutaneous hemorrhages and desquamation, eyes fixed, reflexes lost, respiratory distress, muscular twitching, tremor, incoordination, muscular paralysis, and intense cyanosis. Case fatality rate is close to 60%.

Best prevention is complete avoidance of eating puffers. The sale of puffers in Japan is governed by regulation. Puffer cooks and restaurants must be licensed. Proof of experience in preparing puffers is required.

Poisons of Fungal Origin. Possibly, the most publicized of the foodborne diseases of fungal origin is that caused by the mycotoxins present in certain varieties of mushroom. There are however, a number of mycotoxicosis diseases emanating from other fungal sources. Reported in some detail here is mushroom poisoning and aflatoxicosis.

Mushroom Poisoning. Some authorities believe that enthusiasm for so-called organic foods and experimentation with natural hallucinogens have probably contributed to the increased incidence of serious and fatal mushroom poisoning that has occurred in the United States. Warnings ad infinitum pertaining to the danger of foraging for mushrooms have not proved entirely adequate to prevent tragic cases of poisoning by wild mushrooms. These cases especially occur in the fall when the mushrooms, which are in the reproductive part of the fungus, can be easily harvested. Experience has indicated a wide range of susceptibility to mushroom toxins among individuals. Also, the severity of the poisoning may depend upon the season, the degree of maturation of the mushrooms, and logically the number of mushrooms ingested.

The etiologic agents are cytotoxins, the most important of which is amatoxin produced by mushrooms belonging to the genera *Amanita* and *Galerina*. These include those mushrooms commonly referred to as death angel, death cup, destroying angel. The so-called "false morel" mushrooms of the genus *Helvella* are also implicated. Case fatality rate from poisonings by *Amanita* and *Galerina* approach 50%, while with *Helvella* the fatality rate is considerably lower. It must be emphasized that just one or two mushrooms ingested can cause death.

Mushroom toxins are a protoplastic poison that disrupts integrity of cellular membranes. The amatoxin molecule is a complex protein, a cyclic octapeptide (Fig. 7) that, upon ingestion, inhibits ribonucleic acid polymerase II in the victim's cells, thus interfering with protein synthesis. In turn, this results in damage to membranes of cell walls, of organelles, and of nuclei. Lethal hepatic and renal tubule destruction may occur after ingestion of but one cap containing amatoxin. Authorities do not agree as regards the toxicity of phalloidine, a similar substance with a 7-membered cyclopeptide ring structure, which is produced by *Amanita phalloides*.

Early symptoms include abdominal pain, followed by severe vomiting, diarrhea, and fever. Dehydration, hypovolemia, and electrolyte loss may ensue, and hematuria and blood-streaked diarrhea also may occur. After a day or two, the gastrointestinal symptoms abate and the patient may appear to improve. However, by the third or fourth day, hepatic and renal failure become evident. Jaundice, hypoglycemia, oliguria, bleeding, delirium, and coma supervene and, in cases this advanced, 40 to 90% of the patients die. Laboratory confirmation of the presence of amatoxin can be obtained by performing thin-layer chromatographic analysis of samples of mushrooms or of vomitus, gastrointestinal aspirates, or stool specimens.

Supportive measures used by treating physicians will include the correction of fluid and electrolyte depletion, important during the initial phase of treatment. Hemodialysis has been used in acute renal failure.

Toxin ingestion from some mushrooms (or at varying times) may be neurotoxins that are less dangerous than mushroom cytotoxins. Muscarin is one of these neurotoxins. Onset of the illness is rapid. Symptoms include salivation, perspiration, peripheral vasolidation, lacrimation, bradycardia, nausea, vomiting, abdominal cramps, copious watery diarrhea, slow, irregular

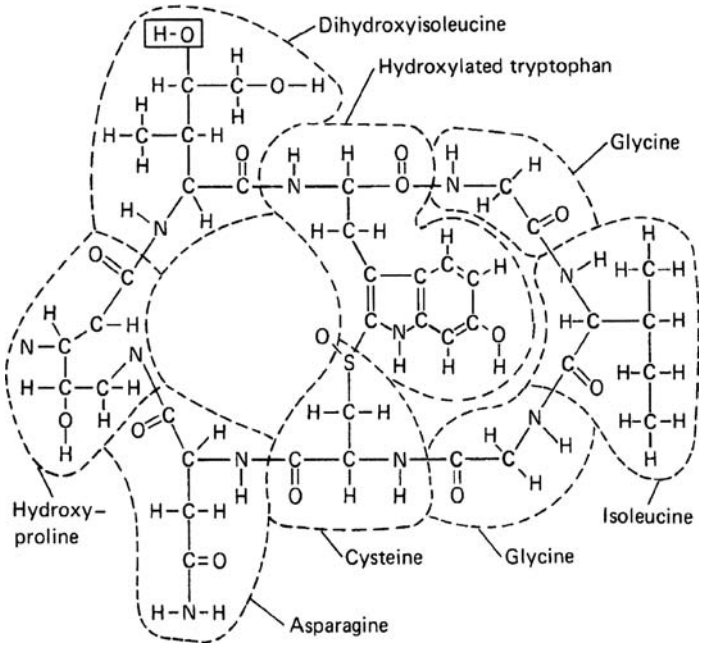

Fig. 7. Amatoxins appear to be made up of eight amino acids (within the dotted lines). These are joined by peptide bonds and thus a continuous cyclopeptide ring is formed. It will not be noted that a sulfur atom serves to link the side chains of two of the amino acids and thus a bridge across the ring is created. The OH group contained within the box (for illustrative purposes here) is apparently critical to this molecule's toxicity. The specific toxin illustrated here is alpha-amanitin.

pulse, pupil constriction, asthmatic breathing, cardiac or respiratory failure (rare). Sensorium is ordinarily clear. Other neurotoxins, with somewhat similar effects, include ibotenic acid, muscimol, uscazone, trichloromic acid, and psilocin. The latter produces psychotomimetic manifestations, causing elevated mood, laughter, hallucinations.

Mushroom-alcohol intolerance is an interesting aspect of certain mushroom reactions. This occurs when alcohol is consumed (ranging from within 24 to 48 hours) after ingesting inky cap mushrooms (*Coprinus attramentarius*). This also occurs in connection with the species *Clitocybe claviceps* when ingested along with, or before beer or sake. Apparently, the disulfiramlike (antabuse) constituents of mushrooms interfere with normal metabolism of alcohol. Normally onset of the illness appears within 1/2 to 2 hours. Symptoms include flushing (purplish-red face), metallic taste, paresthesia of extremities, palpitation, dyspnea, hyperventilation, tachycardia, feeling of swelling hands, nausea, and vomiting. Attacks usually last from 30 minutes to several hours. Prevention is the abstention from alcohol for several days after consuming either of these varieties of mushrooms, and particularly avoiding overheating *C. atramentarius*. Some authorities suggest avoidance of the latter species altogether.

Aflatoxicosis (Aflatoxin Poisoning). The etiologic agents of this foodborne illness are Aflatoxin B_1, B_2, G_1, and G_2 from the *Aspergillus flavus-oryzae* group. These fungi are found worldwide and they grow on practically any substrate. They are carcinogenic to rats, ducks, and trout and some authorities implicate them in involvement with human cancers. These toxins are heat-stable. Suspect food sources include cottonseed meal, Brazil nuts, palm kernels, groundnuts (peanuts), corn (maize), other cereals, and animal feeds. Preventive measures include control of moisture during storage of aforementioned materials, prevention of damage during harvesting, insect control, fungicidal mold control, and physical removal of contaminated products, such as groundnuts.

Onset of the illness may require a few weeks. Symptoms include low-grade fever, jaundice, ascites, and edema of feet. Fatty infiltration and cirrhosis of liver also may occur. The appearance of aflatoxin is usually random and unpredictable.

Poisons of Parasitic Origin. Parasitic diseases always or usually transmitted by foods include trichinosis, diphyllobothriasis, and anisakiasis. Amebiasis (amoebic dysentery) is also food and water related. See also **Amebiasis (Amebic Dysentery)**. Toxoplasmosis is also food related. See also **Toxoplasmosis**.

Trichinosis (Trichinelliasis). The etiologic agent is *Trichinella spiralis*, threadlike roundworms (nematodes). The larva excyst in duodenum, females invade mucosa of small intestine, larvae travel via blood and lymph, encyst in muscle, the incubation period varies from 4 to 28 days, but usually requires about 9 days. In the first stage of the disease (intestinal invasion), symptoms include nausea, vomiting, diarrhea, abdominal pain. In the second stage (muscle penetration), there may be an irregular, but persistent fever, edema of the eyes, profuse sweating, muscular pain, thirst, chills, skin lesions, weakness, prostration, labored breathing. In the third stage (tissue repair), there may be generalized toxemia, myocarditis. There will be a high eosinophil blood count.

Because of muscular involvement, there are difficulties with speech, swallowing, and chewing, and usually swelling of the upper eyelids, a characteristic of the disease. Mild cases usually run their course in about 2 weeks; severe cases about 6 weeks. Seldom does any permanent muscle damage result. Contaminated food sources may include pork, bear meat, walrus flesh, and dog meat. Best prevention is by careful control over pork production, making certain that garbage is not fed to pigs. Thorough cooking of all pork also is an excellent safeguard.

Diphyllobothriasis. The etiologic agent is *Diphyllobothrium latum* (broad or fish tapeworm). The flatworm (cestode) attaches to mucosa of small intestine. Length may be 30 feet (9 meters) or more. Symptoms are often trivial or absent. Nausea, vomiting, weakness, dizziness, diarrhea or constipation and anemia may occur in serious cases. Deficiency of vitamin B_{12} may occur because of competition of worm for this vitamin. Treatment with one of several antihelminths, such as oleoresin aspidium or quinacrine, is usually successful.

Most common food sources are raw or partly cooked or inadequately pickled freshwater fish, such as pike and pickerel.

Anisakiasis. The etiologic agent in *Anisakis* spp., a roundworm (nematode). The adult worm lives in the intestine of fish-eating sea mammals. Larvae are found in herring. Outbreak reports have been made in the Netherlands, Japan, the United Kingdom, and the United States. Herring is the likely contaminated food source, particular if raw or partially cooked and pickled or smoked. The best prevention is thorough cooking of herring. Or, freshly caught fish can be frozen at $-4\,^{\circ}$F ($-20\,^{\circ}$C) and held for 24 hours; or the fish can be preserved with high concentrations of sodium chloride and held for 10 days.

Listeriosis. This illness is caused by *Listeria monocytogenes*, one of the latest pathogens to emerge as a foodborne disease. The disease occurs in predisposed humans and has a case fatality rate of about 30%. Symptoms include diarrhea, nausea, and vomiting. Outbreaks have been reported in Massachusetts, California, Canada, the Netherlands, England, Wales, and New Zealand. Outbreaks can involve different serotypes.

The HACCP System

This system, the "Hazard Analysis and Critical Control Point" health safety system, was pioneered in the 1960s. It was founded by the U.S. Army Natick Research and Development Laboratories, the National Aeronautics and Space Administration (NASA), and the Pillsbury Co. (Minneapolis) in connection with the development of a "foods for space" program. The system received slow, but continuing acceptance, particularly in the late 1980s and into the early 1990s. The system is based partly on the philosophy that final-product testing is not the principal key to success in ensuring safety. Rather the control of processing and handling food products from raw materials to the instant of consumption is required. This is a lesson that Japanese food manufacturers and distributors learned many years ago. In 1985, the National Academy of Sciences (U.S.) recommended that the HACCP be the basis for all food regulatory agencies. Web reference. http://vmctsan.fda.gov/~lrd/haccp.html.

In 1987, the National Advisory Committee on Microbiological Criteria for Foods (NACMCF) was established. By 1989, a total of seven principles became the backbone of the HACCP system[1]:

1. **Conduct Hazard Analysis and Risk Assessment** A hazard is defined as any biological, chemical, or physical property that may cause an unacceptable consumer health risk. All the potential hazards in the food chain are analyzed from growing and harvesting

[1] As described by W.H. Sperber (The Phillsbury Co.).

to manufacturing, distribution, retailing, and consumption of the product.

2. **Determine CCPs** A CCP is any point in the process where loss of control may result in an unacceptable health risk. A CCP is established for each identified hazard. It is within this principle that the dynamic nature of HACCP is most evident. The emergency of foodborne listeriosis has taught food processors the importance of potential product contamination from the processing environment. Thus, cleaning and sanitation procedures are included as CCPs.
3. **Establish specifications for Each CCP** Experience has shown that it is necessary to spell out tolerances at each CCP. Examples of specifications include product pH range, the maximum allowable level of antibiotic residues, the time and temperature range for pasteurization, and the minimum particle size for metal detection.
4. **Monitor Each CCP** A regular schedule for monitoring each CCP is necessary. At a minimum, this would be once per shift change, or hourly, or even continuously. A published testing procedure for monitoring each parameter should be available to personnel. Responsibility for monitoring must be clearly assigned. Test results must be recorded. Portable computers can facilitate this procedure.
5. **Establish Corrective Action** Corrective actions for each CCP must be outlined and specific responsible personnel would effect and report the corrective action taken.
6. **Establish a Recordkeeping System** An effective recordkeeping system is mandatory so that in an extreme case, product recalls can be effected.
7. **Establish Verification Procedure** This principle is important where HACCP-based regulatory procedures have been adopted. The process of risk assessment, established in the 1970s, three hazard classifications were established, including (a) product contains sensitive ingredient, (b) no process step was taken to eliminate hazard, and (c) potential for product abuse was evident. Several new criteria were added in the early 1990s:

    1. **Food Intended for Consumption by "At-Risk" Population** Persons at particular risk (above the general population) must not be overlooked. These persons include: the very young, the elderly, and the infirm, who are particularly susceptible to salmonellosis. Immunocompromised people are more susceptible to listeriosis than the general populace. Persons undergoing chemotherapy or organ transplantation frequently are immunocompromised. This situation is of particular important in food products designed for hospitals and nursing home consumption.
    2. **Product Contains Sensitive Ingredient** A sensitive ingredient is any potential carrier of a hazard, usually a microbiological hazard. Major food manufacturers have established ingredient programs for protection against Salmonella, Staphylococcus aureus, aflatoxin, Bacillus cereus, and Listeria monocytogenes.
    3. **No Process Step taken to Eliminate Hazard** Examples would include absence of heat treatment to kill bacterial pathogens and of physical detecting devices, such as magnets and screens, to detect foreign metallic materials picked up from machinery at some point in the food chain.
    4. **Recontamination Potential Before Packaging** This precaution particularly targets specially chilled foods, the acceptance of which is growing at a rapid rate. Many high-quality convenience foods are designed for freezing or chilling prior to usage. The fact that L. monocytogenes is psychotrophic, capable of growth at refrigerator temperatures, has focused much attention on these foods. Obviously, a chilled food that could be recontaminated before packaging could be more hazardous than a food in which no potential for recontamination existed, such as a food which was pasteurized inside its final sealed package.
    5. **Potential for Product Abuse** The risk assessment must consider the potential for product abuse in distribution, retailing, or consumer handling which could result in an increased hazard. For example, a chilled food that was held at ambient temperature for more than several hours (e.g. on a loading dock), in a car, or at a picnic, could build up hazardous populations of bacteria that would have been inhibited at refrigerated temperatures.
    6. **No Terminal Heat Process** This hazard characteristic was added to account for ready-to-eat foods in the risk assessment process. Since many microbiological hazards by the consumer should have a greater margin of safety than a food which is not heated before consumption. See also **Bacterial Diseases**.

FOOD CHAIN. The series of events that converts solar energy to food for plants and animals; this happens initially by way of photosynthesis. The basic work is accomplished by leaves in the case of terrestrial plants, and by plankton in the sea. Then, more complex creatures consume plants and/or smaller (usually) organisms and so on in a chain of events involving ever increasing sizes and appetites of the consumers and ever decreasing amounts of food available in the chain. Studies have shown that for a human to gain 1 pound (kilogram) as the result of consuming seafood, the sea must generate 1000 pounds (kilograms) of living matter. At the base of the food pyramid or first link in the chain are the trillions of plankton which create the 1000 pounds (kilograms) of basic chemical food. Then, a variety of crustaceans, smaller fishes, and creatures reduce this 1000 pounds (kilograms) to 100 pounds (kilograms). Then, the game and food fishes in their feeding reduce the 100 pounds (kilograms) to 10 pounds (kilograms). To gain 1 pound (kilogram) of weight, the human must consume about 10 pounds (kilograms) of fish. This may be stated more accurately by indicating that the 10 pounds (kilograms) of the fish may sustain 1 pound (kilogram) of weight in the human, these latter factors depending, of course, upon a widely ranging metabolism among individuals.

FOOD PACKAGING. The principal functions of food packaging are to protect the food contents from physical damage, losses, or deterioration, and to facilitate distribution from processor to consumer. Food packaging also must attractively identify the product and perform these functions at minimum system cost because the package itself has no intrinsic value to the consumer. Food packaging represents ~57% of the United States' packaging industry.

Food packaging assists product preservation for distribution by reducing spoilage, infestation, contamination, and pilferage; makes economical use of warehouse space; conserves labor in both distribution and marketing; and permits distribution of identified products that can be effectively marketed through self-service retailing. Food packaging deals not only with the materials in contact with the product, but also with secondary and tertiary (unitizing) packages, form, equipment, labor, consumer use, and systems costs.

The choice of packaging for a given food product is circumscribed by a variety of factors, ie, the food characteristics determine the protection needed to prevent deterioration, and the distribution system affects the product's shelf life and therefore imposes additional requirements for its protection. The food package must be attractive, convenient, and identifiable to the consumer. Its costs must be low, and the machinery to produce it must be available. Food packagers must actively consider the ultimate disposal of the used package in selecting food packaging.

Food deteriorates by biochemical, enzymatic, microbiological, and physical vectors. The biochemical vector is the result of interactions of food chemicals because of their proximity to each other. Enzymatic deterioration is biochemical deterioration catalyzed by enzymes naturally present in food. Microbiological deterioration from yeasts, molds, and bacteria is a common food spoilage vector. Damage to food products not associated with biochemical, enzymatic, or microbial spoilage is usually physical, such as gain or loss of water. Elevated water activity in food products increases the rate of biochemical reactions. In food products with high water content, such as fresh produce or meat, water loss alters physical characteristics and water gain can lead to favorable conditions for microbiological growth. Thus, much of the function of food packaging is to ensure against gain or loss of water. Almost all adverse reactions are accelerated by increasing temperatures.

Packaged Food Classification

Approximately one-half of all the food products in the United States are fresh or minimally processed. Fresh food products include meats, vegetables, and fruits that are unprocessed except for removal from the original environment and limited trimming and cleaning. Fresh foods are handled to retard deterioration, which is relatively rapid at ambient or higher temperature. Meats should be chilled rapidly to $<10\,^{\circ}C$ ($50\,^{\circ}F$) and most vegetables and fruits are generally reduced to $<4.4\,^{\circ}C$ ($40\,^{\circ}F$) by low temperature air, water, or ice.

Minimally processed foods include those that have been altered to help retard deteriorative processes. For example, most dairy products must be refrigerated after pasteurization; salt/nitrite-cured meats must be kept refrigerated after processing to minimize microbial growth.

Fully processed foods are intended for long-term shelf life at ambient temperature, and include almost all heat processed, dried, etc, foods. See also **Food Processing**.

Fresh Foods

Meat, Poultry, and Fish. About a quarter of food products in the United States are meats, including beef, poultry, seafood, lamb, veal, and pork. All of these are susceptible to microbiological, enzymatic, and physical changes.

The color of red meat depends on oxygen. The natural color of the meat pigment myoglobin is purple. The bright red color of the fresh-as-cut meat is from oxymyoglobin. To preserve red meat, the objectives are to retard microbiological enzymatic and biochemical spoilage and weight loss, and to deliver red color at the consumer level.

In distribution channels, most red meat is packaged under reduced oxygen in high oxygen–water vapor barrier flexible packaging materials to retard deterioration. Fresh meats are transported to retail outlets at temperatures $<10\,^{\circ}C$ ($50\,^{\circ}F$) to retard deteriorative processes. At the retail level, exposure to air in gas-permeable packaging permits restoration of the bright red oxymyoglobin color. Oxygen-permeable flexible packaging, such as plasticized poly(vinyl chloride) [CAS: 9002-86-2] (PVC) film, permits oxygen into the package while retarding the passage of water vapor. Case ready fresh meat is often packaged under elevated carbon dioxide/oxygen in gas barrier package structures, such as ethylene–vinyl alcohol (EVOH) in combination with polypropylene [CAS: 9003-07-0] or polystyrene [CAS: 9003-70-7] to retard microbiological growth and retain the oxymyglobin red color.

Poultry, susceptible to microbiological deterioration, is an excellent substrate for *Salmonella*, a pathogen. Therefore, the temperature is reduced as rapidly as possible after slaughter and dressing. Packaging at factory level is in soft film, ie, low density polyethylene [CAS: 9002-88-4], which retard water vapor loss and permits oxygen entry. Much poultry is centrally packaged in case-ready format.

Seafood is packaged to retard weight loss. Packaging for frozen fish generally has low water vapor permeability to permit long-term frozen distribution without freezer burn or surface desiccation. Wrapped or polyethylene-coated paperboard cartons and water vapor barrier flexible films such as polyethylene are employed to package frozen fish.

Produce. Fresh fruits and vegetables must be handled gently because of fragile structures and the ubiquitous presence of microorganisms. Damage to the product surfaces provides channels through which microorganisms can enter to initiate spoilage.

Fresh fruit and vegetable packaging is often in bulk in a variety of traditional wooden boxes and crates, and corrugated fiberboard cases. At or near the retail level, bulk produce may be repackaged in oxygen-permeable flexible materials, such as PVC, with or without a tray of expanded polystyrene containing absorbent pad to help control drip.

Partially Processed Food Products. Partially processed food products have received more than minimal processing, but still require refrigeration.

Nitrite-Cured Meats. Ham, bacon, sausage, bologna, etc, are cured to reduce water activity, are spiced for flavor, and usually have ingredients to maintain the desired red color. Curing agents include salt [CAS: 7647-14-5], sodium nitrite [CAS: 7632-00-0], and sodium nitrate [CAS: 7631-99-4]. Cured meats maintained in an absence of oxygen in vacuum or vacuum plus gas flush have refrigerated shelf lives measured in weeks. Most processed meats are packaged under reduced oxygen on thermoform–vacuum–gas flush–seal systems, usually gas barrier nylon-based, and are distributed under refrigeration. Quantities of cured meats are packaged in oxygen barrier film pouches under inert atmosphere such as nitrogen [CAS: 7727-37-9]. Some barrier film pouches are packaged in reusable polyolefin thermoformed tubs. See also **Food Additives**.

Dairy Products. Dairy products are derived from milk, which must be treated to reduce microbial counts. Pasteurization, a low heat process that destroys disease microorganisms, does not destroy all microorganisms that cause spoilage. Pasteurized dairy products must be maintained under refrigeration. Nonreturnable packages, such as blow-molded high density polyethylene bottles or polyethylene-coated paperboard gable-top packages are most often used for packaging and distributing milk under refrigeration in the United States. In Canada, flexible pouches for fluid milk packaging are made from medium density polyethylene. In recent years, higher heat treatments, eg, ultrahigh temperature (UHT)–short time has been applied in conjunction with clean filling of treated polyester bottles to produce extended shelf life (ESL) packaged products capable of up to 90 days of refrigerated shelf life.

In aseptic packaging, milk is sterilized, ie, rendered free of microorganisms usually by UHT technologies. Simultaneously, high barrier paperboard–foil–plastic-lamination or all-plastic packaging material is sterilized often by hydrogen peroxide. The two are assembled in a sterile environment and the package is sealed to produce sterile milk in a sterile package. The increased heat required for sterilization of the milk can lead to flavors different from those in pasteurized refrigerated milk. Aseptically packaged milk may be distributed at ambient temperature.

Cheese products generally must be maintained under refrigeration using closed flexible plastic, or plastic cups or tubs for packaging. Cured cheeses are often packaged under high CO_2 conditions in gas barrier structures. Ice cream packaging is generally minimal, ie, lacquered or polyethylene extrusion-coated paper-board cartons, molded plastic tubs, or spiral or convolute wound composite paperboard tubs or cartons.

Fully Processed Foods. Fully processed foods are processed and packaged so that the ambient temperature shelf life can exceed 3–6 months.

Canned Foods. The canning process thermally destroys all microorganisms and enzymes and maintains sterility by hermetic sealing in oxygen- and water vapor impermeable packaging that excludes microorganisms. Whether a metal can, glass jar or barrier plastic tray or pouch is used, the process begins with treating the food product prior to filling. Air that can cause oxidative damage is removed from the interior; however, air removal leads to an anaerobic condition that can foster the growth of pathogenic *Clostridia* organisms. The package is hermetically sealed and then subjected to heating. The package must be able to withstand heat up to 100 °C (212 °F) for high acid products and 127 °C (260 °F) for low acid products, which must receive added heat to destroy heat-resistant potentially pathogenic microbial spores. Packages containing low, >pH4.5, acid foods must withstand pressure or the processing operation must be under precise pressure conditions. The thermal process is calculated on the basis of time required for the most remote portion of the food within the package to achieve a temperature that destroys *Clostridia* spores. After reaching that temperature, the package must be cooled rapidly to retard further cooking and biochemical change.

The package must contain the product, exclude air, and withstand heat. It also must maintain a hermetic seal throughout distribution and ensure that no microorganisms can re-enter the package.

The retort pouch, under development for many years, has a higher surface/volume ratio than a can and employs a heat seal rather than a mechanical closure. Similarly, barrier plastic retort trays have higher surface/volume ratios and are usually heat seal closed. Plastic cans intended for microwave reheating are composed of bodies fabricated from multilayer plastic including a high oxygen barrier material, plus double-seam aluminum closures.

Frozen Foods. Freezing reduces temperature to below the freezing point of water so that microbiological, enzymatic, and biochemical activities are virtually halted. In commercial freezing, the product temperature passes through the transition from liquid water to ice rapidly so that ice crystals are relatively small and do not physically disrupt food cells. The product may be frozen inside or outside of the package. Most freezing processes use high velocity cold air or liquid nitrogen to remove heat from bulk or individually quick frozen (IQF) unpackaged product. The frozen product is then packaged in polyethylene-coated paperboard cartons, or polyethylene or polyethylene-coated paper pouches.

Products frozen in the United States include precooked, processed entrees in meal-size portions packaged in microwaveable crystallized polyester trays with polyester film closures, and overpackaged in printed paperboard cartons or in polyester coated paperboard trays.

Dry Foods. Dry products include those dried from liquid form and engineered mixes of dried components blended to become dry products. In the first category are instant coffee, tea, and milk. The liquid is spray-, drum-, or air-dried to remove water; the presence of water at >1% can lead to browning. Engineered mixes include beverage mixes, eg, sugar [CAS: 57-50-1], citric acid [CAS: 77-92-9], color, flavor, and soup mixes, ie, dehydrated soup stock, noodles, and some fat products that become a heterogeneous liquid on rehydration. Products having relatively high fat, such as bakery or soup mixes, must be packaged so that the fat does not interact with the packaging materials. Seasoning mixes that contain herbs and volatile flavoring components can interact with plastic packaging materials such as interior polyolefins. The package must be hermetically sealed, providing a total barrier against both access by water vapor and by oxygen for products susceptible to oxidation. See also **Coffee**; **Tea**; and **Milk And Milk Products**.

Fats and Oils. Cooking oils and hydrogenated vegetable shortenings contain no water and so are stable at ambient temperatures. Unsaturated fats and oils are subject to oxidative rancidity; both usually are packaged under inert atmosphere such as nitrogen. Hydrogenated vegetable shortenings generally are packaged in composite paperboard cans with nitrogen to ensure against oxidative rancidity. Edible oils are packaged in blow-molded polyester bottles.

Margarine and butter and analogous bread spreads contain fat plus water and water-soluble ingredients, eg, salt and milk solids that impart flavor and color to the product. Generally, these products are distributed at refrigerated temperatures to retain their quality. Greaseproof, ie, fat resistant, packaging, such as polyethylene-coated paperboard, aluminum foil/paper, parchment paper wraps, and polypropylene tubs, is used for butter and margarine.

Cereal Products. Breakfast cereals are susceptible to moisture absorption and require good water vapor and fat barrier packaging that also retains delicate flavors. Breakfast cereals are packaged in polyolefin coextrusion films in the form of pouches or bags within paperboard carton outer shells. Sugared cereals are sometimes packaged in aluminum foil or barrier plastic, eg, ethylene vinyl alcohol, laminations to retard water vapor and flavor transmission.

Soft baked goods such as breads, cakes, and pastries are highly aerated structures and are subject to dehydration and staling. In moist environments, baked goods are also subject to microbiological deterioration as a result of the growth of mold and other microorganisms. To retard moisture loss, good water vapor barriers such as coextruded polyethylene film bags or polyethylene-coated paperboard are used for packaging.

Hard baked goods, such as cookies and crackers, have a relatively low water and high fat content. Water can be absorbed, and the product loses its desirable texture and becomes subject to lipid rancidity. Packaging for cookies and crackers includes polyolefin-coextrusion film pouches within paperboard carton shells, and polystyrene trays overwrapped with polyethylene or oriented polypropylene film. Soft cookies are packaged in high water vapor barrier laminations containing aluminum foil.

Salty Snacks. Salty snacks include dry grain or potato products such as potato and corn chips, and roasted nuts. These snacks usually have low water content and relatively high fat content. Snack packaging problems are compounded by salt, a catalyst for lipid oxidation in the product formulations. Snacks are often packaged in pouches derived from oriented polypropylene, metallized oriented polypropylene or polyester film structures that have low water-vapor transmission, relying on rapid and controlled product distribution to obviate fat oxidation problems. In recent years, inert gas, ie, nitrogen flushing has been applied to retard oxidative biochemical changes. Some salty snacks are packaged under inert

atmospheres in both pouches and rigid containers, such as composite and extrusion blow molded polyolefin barrier canisters, to extend distribution. Generally, light which catalyzes lipid oxidation harms such products, and so opaque packaging is often, but not always, employed.

Candy. Chocolate is subject to flavor or microbiological change. Inclusions such as nuts and fillings such as caramel are susceptible to water gain or loss. Chocolates, which are stable, are packaged in greaseproof papers and moisture–fat barriers, such as polypropylene film.

Hard sugar candies have very low moisture content. They are sealed in low water vapor transmission packaging such as aluminum foil or oriented polypropylene film.

Beverages. Beverages may be still or carbonated, alcoholic or nonalcoholic. The largest quantity of packaging in the United States is for two carbonated beverages, ie, beer and soft drinks. Both contain dissolved carbon dioxide [CAS: 124-38-9] creating pressure within the package. The package must be capable of withstanding the internal pressure of carbon dioxide. Coated aluminum cans, and glass and polyester plastic bottles are the most used packaging for carbonated drinks.

Beer is more sensitive than other carbonated beverages to oxygen, loss of carbon dioxide, off-flavor, and light. Most American beer undergoes thermal pasteurization performed after sealing in the package. In recent years, some beer has been packaged in polyester containing added oxygen barrier and oxygen scavengers often in the form of, for example, nylon MXD6. The internal pressure within the package can build to well over 690 kPa (100 psi) at 63 °C (145 °F), the usual pasteurization temperature. Beer and other carbonated beverages are generally packaged at relatively high speeds; therefore, the packages must be extremely uniform, free of defects, and dimensionally stable.

Paper, Metal, and Glass Packaging

Paper. The largest volume packaging materials in the United States, accounting for 40% of all food packaging, are paper and paperboard. Paper consists primarily of cellulose fibers obtained from wood by pulping. See also **Paper**; **Papermaking and Finishing** and **Pulp (Wood) Production and Processing**. The packaging properties of paper, its strength, and mechanical properties depend on the treatment of the wood fibers and on the incorporation of fillers (qv) and binding materials at the paper mill. The physicochemical properties of paper and paperboard, such as permeability to vapor and gases, are derived from impregnation, coating, and/or laminating. Materials used to enhance barrier include plastics, such as polyethylene, and resins, such as urea–formaldehyde. Laminated and coated papers often warrant the designation of protective materials. See also **Barrier Polymers**. Many converted papers, however, offer little more than protection from light and mechanical damage.

Paper may be used as flexible packaging material components or as material for construction of rigid containers. Flexible packaging applications include bags, usually multiwall; liners; liner substrates; pouches; and overwraps. Some of the more important types of paper used for these purposes include Kraft paper, grease-proof papers, glassines, and, infrequently, waxed papers. Glassine grades are made of tightly knit Kraft paper fibers, highly supercalendered to deliver smooth surfaces capable of accepting coating and print. Greaseproof grades are similar to glassine except for the finishing, and so are not as readily printable. Both glassine and greaseproof papers have good oil resistance.

Rigid paperboard containers are made of paper greater than 0.254 mm (0.010 in.) in caliper and include folding cartons, corrugated fiberboard cases, and spiral and composite wound composite cans. Many paperboard cartons require the use of inner liners or overwraps, made of protective grades of paper, plastic, or aluminum foil laminations.

Folding Paperboard Cartons. Valued at >$8 billion, paperboard folding cartons are produced in more than 450 plants, many of which are connected with paperboard mills. nearly 40% of paperboard folding cartons are food and beverage packaging. Among the 10 largest producers, which account for one-half of the industry sales, are smurfit stone, http://www.smurfit.com:8080/content/, Mead Westvaco, http://www.meadwestvaco.com/corporate.nsf, International Paper, http://www.internationalpaper.com/, Rock-Tenn, http://www.rocktenn.com/, and Graphic Packaging http://www.graphicpkg.com/intro.html. Paperboard folding cartons protect food products from impact and crushing. Certain dense or easily flowing products can be held in shape better by the carton structure. Generally, folding paperboard cartons are used to contain < 1.36 kg (3 lb) of product. Paperboard for noncontact food packaging has an interior flexible liner that prevents direct contact between the product and the paperboard of the carton. Up to one-half of the paperboard folding cartons are manufactured from recycled paper and paperboard, used newspapers, and some postconsumer waste papers.

Carton liners, eg, coextruded polyolefin pouches, help to prevent loose product content sifting and moisture migration. The carton provides a surface for graphic decoration. Polyethylene extrusion coating or, in some cases, polyethylene blend hot melt coatings are used for the interior or exterior of folding cartons, especially if used to contain liquids. Extrusion coatings can be used with cartons when higher levels of water–water vapor protection are indicated and a film overwrap or inner liner is not desired. Coatings are usually less effective than an additional layer, such as an inner liner.

Composite Paperboard Canisters. Composite canisters usually consist of spiral or convolute wound paperboard or paperboard-laminated body, the ends of which have been formed to accept paper ends or flanged to seam a metal end or to heat seal a flexible lid. The package usually has a printed paper label covering the entire body. Composite paperboard canisters using aluminum foil interior are used for packaging refrigerated cookie and biscuit doughs, snack foods, juice concentrates, and dry powders. Convolute wound canisters have been used for cocoa powder, roasted and ground coffee, candy, and ice cream.

Shipping Containers. A majority of food products are distributed in corrugated fiberboard case trays engineered to meet specifications under quasi-governmental regulations. Corrugated fiberboard is the material most widely used throughout the world for tertiary or distribution packaging. Printed, cut, and fabricated into a box or tray, corrugated fiberboard forms the shipping case. The largest single packaging material in the United States is corrugated fiberboard. Food packaging represents nearly 40% of the total usage. Most converters are linked to paperboard mills. Among the largest producers are Smurfit Stone, http://www.smurfit.com:8080/Content/, Georgia Pacific, http://www.gp.com/, Weyerhaeuser, http://www.weyerhaeuser.com/, Inland, and Rock-Tenn http://www.rocktenn.com/.

Polyethylene shrink film wrapping of corrugated fiberboard trays is in common use in and outside of the United States. Equipment erects the trays, fills the trays with primary packages such as cans or jars, wraps the grouping in shrink film, and heat shrinks the combination. Shrink film wrapping keeps primary and secondary packaging materials clean and dry.

Metal Can Packaging. Nearly 130 billion metal cans are produced annually in the United States, of which 100 billion are two-piece aluminum used for beer and carbonated beverage packaging, but with increasing numbers for still beverage packaging. About 30 billion of the cans are three- and two-piece steel for food containment. The leading merchant can manufacturers are Crown Cork and Seal, http://www.crowncork.com/, Rexam, http://www.rexam.com/sectors/index.asp?pageid=7, and Ball.

Two-Piece Cans. Almost all aluminum cans are two-piece drawn and ironed, but some are drawn and redrawn. About one-half of steel cans are two piece.

Draw and iron manufacturing starts with a coil of metal fed into a multiple cupping or blanking press that forms it into shallow cups. These cups are fed into an ironing press, where successive rings or a die stack form the can side wall. More metal is left near the top and bottom to give added strength. In addition to thinning the side wall of the shell, the ironing press imparts the bottom profile. Trimming of the top end follows to produce a can of uniform height. Aluminum and steel drawn and ironed cans are manufactured by essentially the same process.

Inside coatings to protect both the metal and the contents are applied to the can by an airless spray gun. After application, the cans are baked in an oven to remove the solvent and cure the coating.

Three-Piece Cans. Most steel cans are three-piece, ie, a body and two ends. In the past, solder was used to bond the longitudinal seam or "tin" cans, but tin-plate has been replaced by chrome/chrome oxide, and solder has been replaced by welded side seams.

For welded side-seam cans, sheets of steel are coated, baked, and slit into body blanks. The blanks are fed into the bodymaker, where the edges are cleaned to remove any interfering layer, where the steel is welded. The blank is formed into a cylinder with the edges overlapped at the side seam and tack welded together. The cylinder is then passed between rotating

wheel electrodes, which weld each side of the seam. Side-seam coating coverage is achieved by applying a powdered epoxy material to both sides of the seam immediately after welding. Residual heat from the weld fuses and cures the stripe.

The cylindrical body then travels to the flanger where the top and bottom edges are curled outward to form the flange. Roll or die-necking are incorporated to reduce the can body diameter on each end in combination with flanging.

When the flanged, or necked and flanged, bodies leave the flanger after having received the topcoat spray and bake, they proceed to the double seamer, where one end is applied.

Protective Coatings. The primary function of interior can coatings is to prevent interaction between the can and its contents. Exterior can coatings may be used to provide protection against the environment, or as decoration to give product identity as well as protection.

Enamel is applied to steel in the flat before fabrication if for three piece cans. Cans manufactured by the draw and ironing operation must be coated internally after fabrication because of the metal deformation with surface disruption that takes place.

Types of internal enamel for food containers include oleoresins, vinyl, acrylic, phenolic, and epoxy–phenolic. Historically, can lacquers were based on oleoresinous products. Phenolic resins have limited flexibility and high bake requirements, but are used on three-piece cans where flexibility is not required. Vinyl coatings are based on copolymers of vinyl chloride and vinyl acetate dissolved in ketonic solvents. These can be blended with alkyd, epoxy, and phenolic resins to enhance performance. Flexibility allows them to be used for caps and closures as well as drawn cans. Their principal disadvantage is high sensitivity to heat and retorting processes; this restricts their application to cans which are hot filled, and to beer and beverage products.

Epoxy phenolic coatings either are made by blending of a solid epoxy resin with a phenolic resin or are the products of the precondensation of a mixture of two resins. A three-dimensional (3D) structure is formed during curing, which combines the good adhesion properties of the epoxy resin with the high chemical resistance properties of the phenolic resin. The balanced properties of epoxy phenolic coatings have made them almost universal in their application on food cans.

Vinyl organosol coatings, which incorporate a high molecular weight thermoplastic PVC organosol dispersion resin, are extremely flexible. Soluble thermosetting resins, including epoxy, phenolic, and polyesters, are added to enhance the film's product resistance and adhesion.

Two basic methods are used for the application of protective coatings to metal containers, ie, roller coating and spraying. Roller coating is used if physical contact is possible, eg, coating of metal in sheet and coil form. Spraying techniques are used if physical contact is not possible, eg, to coat the inside surface of two-piece drawn and ironed can bodies.

Coatings that are applied wet must be dried after application by solvent removal, oxidation, and/or heat polymerization. Using powder coating, the resin is applied dry in the form of a fine powder, usually under the influence of an electrostatic field. Powder coating is used where heavy coatings are required, eg, in the protection of welded side seams where the bare metal that exists in the weld area must be covered. Curing is usually by infrared (ir) radiation or high frequency induction heating.

Polyester and polypropylene films have been laminated to base steel sheet to impart protection to the metal. These laminated metals are used to make three- or two-piece drawn cans.

Environmental Aspects. More than two-thirds of aluminum cans are recaptured and returned for recycling into more cans. Because of the heat of melting, the use of postconsumer recycled cans is safe for beverage contents. Not only does recycling save on mass of materials, it also saves the energy of manufacture from aluminum ore.

Because of the vast quantities of scrap steel available from automobiles and appliances, recycling of steel cans has been growing at a relatively modest rate. A third of steel cans are returned and remelted.

Glass Packaging. Glass is used for carbonated beverages, beer, and still beverage packaging. This $4.5 billion industry is declining in importance because of weight, relative fragility, and energy requirements. Glass is recyclable, and so cullet, or crushed reused glass, is a part of every raw material batch. Glass is virtually chemically inert and impermeable.

Protective coatings capture or retain some of the original strength of glass containers and delay deterioration. Coatings include hot end treatments in which newly formed hot bottles are subjected to an atmosphere of vaporized metallic compound. This atmosphere reacts with the glass surface, chemically bonding to form a primer that provides permanency to the cold end treatment. The second step of the protective coating, usually an emulsion of polyethylene, is applied after the cooling section of the annealing layer, usually at a bottle temperature of ~149 °C(~300 °F). The second coating imparts lubricity to the container surface. This prevents abrasions or other surface damage from bottle-to-bottle or bottle-to-guide rail contact during normal package handling.

To produce glass bottles or jars, the mixture is prepared in unit batches. Mixing is critical because complete homogeneity of the batch is necessary to produce quality glass. Cullet is added to the batch, usually at discharge from the mixer. The cullet must be of the same color and basic composition, and be free of contamination, such as metal bottle caps and tramp metal scraps.

Molten glass moves through the melter to the refiner, where the glass is conditioned for uniform temperature and for release of dissolved glasses to remove seeds and blisters. The molten glass is cooled and conditioned for equalization of temperature throughout the stream. The glass melting process, regardless of the type of furnace or energy source, is designed to supply a definite tonnage of glass per unit time. Continuous regenerative type furnaces fired with either natural gas or fuel oil commonly are used for melting container glass. Electric melting furnaces also are utilized in glass container manufacturing.

At the gob feeder, the forming operation begins. The gob feeder delivers a glass gob shaped such that it enters the blank mold without excessive mold contact, distortion, or reshaping of the glass. Shears cut off a gob of glass. The gob is fed to either a blow and blow, press and blow, or press-only forming operation to produce a container.

In blow and blow operations, the gob of glass (parison) is delivered from the feeder to the blank mold. The gob drops through a guide funnel into the blank mold in the inverted position. Air is applied to settle the gob into the finish, and air is blown in to complete the parison shape.

Press and blow operations are used to produce wide mouth and some narrow neck containers, including beer bottles. The difference between the press and blow operation and the blow and blow operation is that the parison is pressed into shape by a plunger that fills the complete void in the parison.

The rapid transfer of heat and the mechanics of blowing the bottle creates both thermal and mechanically induced stresses in the newly formed bottle. To relieve the stresses, the newly formed bottles are put through a controlled temperature heat annealing process.

Plastic Packaging

Plastic materials represent ~20% by weight of all package materials, about one-half for film and one-half for bottles, jars, cups, tubs, and trays. The principal materials used are HDPE for bottles, low density polyethylene for film, polypropylene (PP) for film, and polyester for both bottles and films.

Plastic packaging materials are thermoplastic, ie, reversibly fluid at high temperatures and solid at ambient temperatures. These materials may be modified by copolymerization, additives in the blend, alloying, and surface treatment and coating. Properties of principal plastic packaging materials are given in Table 1.

Materials

Polyethylene

Low Density Polyethylene. Film is slightly cloudy, has high tensile strength and good water-vapor barrier properties, but high gas transmission. It is employed for shrink and stretch bundling, as drum and case liners, and to package bread, fresh produce, and low sensitivity food products. The material may also be extrusion blow molded into soft sided bottles.

The density of LDPE for film ranges from <0.90 to ~0.93 g/cm^3. The resin is melted in a heated extruder and converted to film by extruding through a circular die. The resulting tube is collapsed and slit into film ranging in gauge from <0.25 mm to >0.75 mm. Some monolayer and coextruded polyethylene films are produced by slot-die casting. Because of its extensibility, LDPE film is usually printed on central impression-drum flexographic presses; modern rotogravure presses permit finer printing.

Linear Low Density Polyethylene. These films from linear LLDPE resins have 75% higher tensile strength, 50% higher elongation-to-break strength, and a slightly higher, but broader, heat-seal initiation temperature

TABLE 1. PROPERTIES OF PLASTIC PACKAGING MATERIALS

than do films from LDPE. Impact and puncture resistance are also improved over LDPE. Water vapor and gas-permeation properties are similar to those of LDPE films.

Linear low density polyethylene films are used in many of the same packaging applications as LDPE.

High Density Polyethylene. These resins range in density from 0.93 to 0.96 g/cm^3 and are more translucent and stiffer than LDPE films, with lower elongation to break. Water vapor and gas permeabilities are slightly higher than those of LDPE. Softening and melting points are high. HDPE materials are not easily sealed on flexible packaging equipment. The HDPE film replaces paper sacks for retail grocery and department store take out bags. The most important packaging use for HDPE is for extrusion blow molding of bottles for milk, water, and nonfoods, such as liquid detergent, motor oil, etc, by companies such as Graham and Continental.

HDPE coextrusions with LDPE, ethylene–vinyl acetate copolymer or ionomer are widely used as liners in food cartons. High density polyethylene film is produced by blown-film extrusion methods, often blowing downward because the weight of the film could cause collapse of an upwardly blowing bubble, as used for low density polyethylene film. See also **Polyethylene**.

Polypropylene. Polypropylene film is produced as either unoriented (CPP) (cast polypropylene) or oriented (OPP) films. Because of extremely poor cold-temperature resistance and a very narrow, short, heat-seal temperature range, CPP film is not widely used for packaging. In film form, the material is a good heat sealant for packages that have later high temperature requirements, eg, retorting. It is used as a transparent bag material for textile soft goods, twist wrap for candy, and other applications. Coextruded films of PP/PE and CPP are used to separate sliced cheese. Unoriented PP is made by extrusion through a slot die.

Oriented polypropylene film (OPP) may be classified as heat-set and non-heat-set, blown and tentered, coextruded and coated. Orientation improves the cold-temperature resistance and other physical properties. Heat-set biaxially oriented polypropylene film (BOPP) is the most widely used protective packaging film in the United States. It is used to wrap bakery products, as lamination plies for potato and corn chips, and for pastas and numerous other flexible pouch and wrapping applications. Nonheat-set OPP is used as a sparkling, transparent shrink-film overwrap for cartons of candy.

Oriented polypropylene film may be manufactured by blown or slot-die extrusion processes. In the slot-die tenter-frame process, polypropylene film is extruded through a flat-die and stretched or oriented in the machine direction. The film is then reheated, gripped along its edges, and stretched outwardly while in longitudinal motion to impart transverse directional orientation. To impart heat-seal properties, it may be coextruded or coated with acrylic or poly(vinylidene chloride) (PVDC). In the lesser-used double-bubble blown film process, the resin is extruded through a circular die, cooled, reheated, and blown again to produce a balanced, biaxially oriented, heat-set film. Film may be coextrusion blown to provide a heat-sealing coating. Film may also be coated with poly(vinylidene chloride) to impart water-vapor, gas-barrier, and heat-sealing properties.

OPP producers have expanded the core, creating a foam structure with lower density, greater opacity, and a stiffer, more paper-like feel. Vacuum metallization increases opacity and water vapor barrier properties.

Oriented polypropylene film has excellent water vapor barrier but poor gas barrier properties; excellent clarity, or opacity in newer forms; and good heat-seal properties in packaging applications. See also **Polypropylene**.

Poly(vinyl Chloride). To be converted into film, poly(vinyl chloride) (PVC) must be modified with heat stabilizers and plasticizers, which increase costs. Plasticized PVC film is highly transparent and soft, with a very high gas-permeation rate. Water vapor transmission rate is relatively low. At present, PVC film is produced by blown-film extrusion, although casting and calendering are employed for heavier gauges.

The principal packaging use of PVC film is as a gas-permeable, but water vapor impermeable, wrap for red meat, poultry, and produce. Sparkle and transparency, combined with the ability to transmit oxygen to maintain red-meat color, offer advantages in these applications. See also **Polyvinyl Chloride (PVC)**.

Polyester. Poly(ethylene terephthalate) (PET) polyester film has intermediate gas and water vapor barrier properties, very high tensile and impact strengths, and high temperature resistance. Applications include use as an outer web in laminations to protect aluminum foil. It is coated with PVDC to function as the flat or sealing web for vacuum/gas flush packaged processed meat, cheese, or fresh pasta. See also **Polyester Film**.

Polyester is manufactured by extrusion through a slot die and biaxially oriented by stretching first in a longitudinal, and then in a transverse direction while still hot, ie, tentering. Polyester film cannot be heat sealed

by conventional methods and is either coextruded or coated for heat sealing. Being heat resistant and almost inextensible, polyester film is used as a substrate for vacuum metallizing and silica coating, processes that improve moisture and gas properties. Vacuum-metallized polyester film is used for packaging wine (qv) and bulk tomato and fruit products.

Nylon. Nylon is the designation for a family of thermoplastic polyamide materials that in film form are moderate-oxygen barriers. The gas-barrier properties are equal to odor and flavor barrier properties important in food applications. Nylon films are usually tough and thermoformable, but are only fair moisture barriers. See also **Polyamide Resins**.

Nylon films are used in lamination or coated form to ensure heat sealability and enhance barrier properties. The largest uses are as thermoforming webs for twin-web processed meat and cheese packaging under vacuum or in an inert atmosphere. Other uses include bags for red meat, boil-in-bags, bag-in-box for wine, and as the outer protective layer for aluminum foil in cookie and vacuum coffee packages.

Poly(vinylidene Chloride). Poly(vinylidene chloride) (PVDC), most of which is produced by Dow Chemical, is best known in its saran, a PVC-copolymerized form. As solvent or emulsion coating, PVDC imparts high oxygen, fat, aroma, and water vapor resistance to substrates such as oriented polypropylene, polyester, and nylon.

Of the common commercial resins and films, PVDC has the best combination of water vapor and oxygen-barrier properties. High crystallinity confers resistance to the permeation of odors and flavors, as well as to fat and oil. Because of its high chloride content, PVDC tends to corrode processing equipment, which increases manufacturing costs and also leads to environmentalist objections. Unlike other high oxygen-barrier materials, PVDC is almost insensitive to water and water vapor.

Copolymer film is produced by extrusion blowing followed by water quenching. In-line, the film is blown, crystallized, and oriented. The PVDC copolymer film is difficult to produce.

Saran film is used to wrap cheese and occasionally for vertical form–fill–seal chub packaging of sausage and ground red meat. Mostly, it is used as the high barrier component of laminations not containing aluminum foil. It is rarely used alone in commercial packaging because it is difficult to seal. See also **Polyvinylidene Chloride**.

Polystyrene. Polystyrene package film has excellent clarity, stiffness, and dimensional stability. Because of high permeability to water vapor and gases, it is suited for packaging fresh fruit and vegetables requiring the presence of oxygen. Packaging applications are limited to folding-carton windows, overwraps for tomato trays, lettuce wrapping, etc.

Expanding polystyrene resin prepared by blending with gas delivers an opaque, low density sheet useful for beverage-bottle and plastic can labels as a water-resistant paper substitute.

Other Films. Although commercially less important than polyethylenes and polypropylenes, a number of other plastic films are in commercial use or development for special applications, including ethylene–vinyl acetate, ionomer, and polyacrylonitrile.

Ethylene vinyl acetate copolymer (EVA) forms a soft, tacky film with good water vapor barrier, but very poor gas-barrier properties that serves it well for packaging fresh-cut produce. It is widely used as a low temperature initiation and broad-range, heat-sealing medium. The film also serves for lamination to other substrates for heat-sealing purposes.

Ionomers, often known by their trade name Surlyn (Du Pont), are ionically cross-linked thermoplastics derived from ethylene–methacrylic acid copolymers. Ionomer films are tough, extensible, and impact resistant with excellent heat-seal and hot-tack characteristics. Extruded on other substrates, ionomer films are used as the heat-sealing component. See also **Ionomers**.

Polyacrylonitrile (PAN) films have outstanding oxygen and CO_2 barrier properties, but only modest water vapor barrier properties. They are for processed-meat and fresh pasta packaging laminations where an oxygen barrier is required for vacuum or gas flush packaging.

Coextrusions. In coextrusion, two or more thermoplastic resin melts are extruded simultaneously from the same die. Coextrusion permits an intimate layering in precisely the quantities required to function. Incompatible plastic materials are bonded with thermoplastic adhesive layers. Coextruded films may be made by extrusion-blowing or slot-casting of two, three, or more layers, eg, AB or ABA. Slot-casting is capable of combining up to 11 layers, but most equipment is used for the simple AB, ABA, and ABC or ACBCA configurations, where C is the adhesive layer. In the simplest combinations, oriented polypropylenes are coextruded with copolymer heat-seal layers. Low density polyethylenes are coextruded to impart toughness or slip characteristics.

In more complex combinations, HDPE, LDPE, and EVA resins are coextruded to produce stiff, heat-sealable films to be used as liners in cereal, cookie, and cracker cartons. Films of EVA and white-pigmented LLDPE are used for packaging of frozen vegetables and fruits. In these applications, one layer imparts toughness, opacity, or stiffness, and the other layer adds heat sealability. Coextrusions of nylon with polyethylene in five layers are used for thermoforming where high gas and water vapor barrier are required, eg, medical packaging.

Plastic packaging materials may be classified into rigid and flexible, with an overlapping dividing line between rigid and flexible. Materials determined by caliper or gauge to have thicknesses less than 0.25 mm are generally regarded as being in the flexible category.

Flexible Packaging. Flexible packaging is composed of both single- and multilayer structures. The latter may be further subdivided into laminated, coated, and coextruded, or combinations of these.

More than one-half of flexible packaging is used for food. Within foods, candy, bakery products, and snack-type foods, such as potato and corn chips, use well over half of flexible packaging. Cheese, processed meat, shrink wraps, condiments, dry-drink mixes, fresh meats, and fresh produce represent smaller applications.

Over 1000 firms participate in the flexible packaging industry in the United States. Manufacturers process the plastic resin into film, a unit operation sometimes assumed by the converter, depending on the material. The processes of slitting, printing, coating, laminating, coextruding, and fabricating into preformed pouches and bags are performed by converters.

Fabrication. Flexible packaging materials may be mono- or multilayer. Monolayer materials are usually films that have been produced by polymer resin melting and extrusion.

Extrusion of polyethylene and some polypropylenes is usually through a circular die into a tubular form, which is cut and collapsed into flat film. Extrusion through a linear slot onto chilled rollers is called casting and is often used for polypropylene, polyester, and other resins. Cast, as well as some blown, films may be further heated and stretched in the machine or in transverse directions to orient the polymer within the film and improve physical properties such as tensile strength, stiffness, and low temperature resistance.

In coextrusion, two or more plastic melts from different extruders are combined into a single die in which the melts are joined. Coextrusion permits precise, small quantities of plastic materials to be intimately bonded to each other.

Free mono- and multilayer films may be adhesive- or extrusion-bonded in the laminating process. The bonding adhesive may be water or solvent based. Alternatively, a temperature-dependent polymer-based adhesive without solvent may be heated and set by cooling. In extrusion lamination, a film of a thermoplastic, such as polyethylene is extruded as a bond between the two flat materials, which are brought together between a chilled and backup roll.

Flexible materials are printed in roll form by rotogravure, flexographic, and web offset printing. In rotogravure printing, a cylinder is engraved with minute depressions or wells that accept dilute solvent-based inks by capillarity. When contacted by the packaging material, the ink is drawn from the wells to the printing surface and the solvent is evaporated to set the ink. In the increasingly popular flexographic printing, the design is elevated above the cylinder surface using rubber-like materials. In offset printing, oil-based ink is in a planographic attitude and printed or offset onto a rubber blanket from which the ink is later removed to the substrate to be printed. Rotogravure printing cylinders are usually considerably more expensive than flexographic printing plates. Offset printing plates are even less expensive. The detail produced by rotogravure and offset is finer than that produced by flexography. Rotogravure is usually used for long production runs and high resolution reproduction, whereas flexography is used for shorter runs and bolder design, and offset is applicable to short run fine design. Both flexography and rotogravure are used to print flexible packaging in the United States. Coatings applied by printing or extrusion protect the printed surfaces.

Some flexible packaging is fabricated by converters into bags and pouches. Bag material is either small monolayer or large multiwall with paper as a principal substrate. Pouches are small and made from

laminations. Bags usually contain a heat-sealed or adhesive-bonded seam running the length of the unit and a cross-seam bonded in the same fashion.

Applications. Preformed bags are opened by the packager, filled with food product, and closed by adhesive, heat sealing, clipping, stitching, etc.

A small quantity of flexible packaging material, usually oriented polypropylene, shrink polypropylene, or polyethylene, is used to overwrap paperboard cartons. The film is wrapped around the carton and sealed by heating. Products such as "boxed" chocolates, candies, and cookies are overwrapped, sometimes by a printed film.

Some heavier gauge flexible materials, usually containing nylon, are thermoformed, ie, heated and formed into 3D shapes. Such structures are used to provide high gas-barrier, heat-sealable containment for processed meat or cheese.

Large quantities of flexible packaging materials are employed in horizontal form–fill–seal machines to enclose contents, sometimes with a hermetic seal. The web of material is unwound and folded so that its longitudinal edges are in contact. Meanwhile, the product is conveyed at the same speed as the flexible packaging material into the tube. The two edges are heat-sealed and transverse heat seals are formed between the product units. This system is used for overwrapping, as well as for unit packaging for candies, cookies, and crackers.

In a variant of the horizontal form–fill–seal operation, the material, moving in a horizontal direction, is folded on itself vertically. Vertical sections of the two faces are heat-sealed to each other to form a pouch, which may then be filled. The pouch, usually made from film or paper bonded to aluminum foil plus a plastic laminant and heat sealant, is closed by a heat seal. This type of pouch gives high moisture and oxygen protection and is used for moisture- and flavor-sensitive condiments and beverage mixes.

The largest volume of flexible packaging is used in vertical form–fill–seal applications for loose, flowable products such as potato and corn chips, nuts, and roasted and ground coffee. The roll of flexible material is unwound over a forming collar forcing the web into a vertical, tubular shape. By heat-sealing the edges and a bottom transverse seal, an open-top tube is formed. The product is gravity filled, the web is drawn down, and the tube is closed by another heat seal. Vertical form–fill–seal operations use water vapor barrier materials, such as oriented polypropylene film to package moisture-sensitive products.

In applications other than protective packaging, flexible materials are employed to unitize cans, bottles, cartons, or cases. Heat-shrinkable films, such as low density or linear low density polyethylene, are wrapped around groups of bottles or cans, sealed, and exposed to hot air to bind the contents tightly together within the film. In stretch wrapping, an extensible film cohesive to itself, eg, linear low density polyethylene, is wrapped very tightly around the contents. Surface cohesion causes the film wrap to hold to itself. As the stretched film attempts to revert to its original unstretched form, it binds the bundle more tightly.

Semirigid Containers. Most semirigid plastic for packaging is in the form of bottles and jars. Jars have openings approximately the same as those of the body, whereas the neck diameter of bottles is significantly smaller than that of the body.

Fabrication Processes.

Injection Molding. Matched metal molds are used in the fabrication of plastic closures, specialty packages, and bottle preforms. In conventional injection molding the plastic resin is melted in an extruder that forces a measured quantity or shot into a precision-machined chilled mold after which the nozzle of the extruder is withdrawn.

The pressure of the extruder forces uniform plastic distribution throughout the mold. Cooling the mold solidifies the plastic with slight shrinkage. The mold is maintained closed by mechanical or hydraulic pressure while the thermoplastic is injected and solidified.

Because cycle time to inject, flow, set, open, eject, and close is finite, and the face area or platen size is limited, the effective molding area is increased by increasing the number of mold cavities so that the number of finished pieces per cycle may be multiplied many times. Injection molds are constructed of metal precision-machined with internal cooling, multiple cavities, and multifaces, and with devices for extraction or ejection of the molded piece.

Returnable distribution cases for carbonated-beverage and milk bottles are injection molded from high density polyethylene or polypropylene–ethylene copolymer. The HDPE and polypropylene–ethylene copolymer cups and tubs for dairy product and specialty frozen food applications are injection molded. High and medium density polyethylenes are injection molded as closures for metal and paperboard composite can closures. Because covers and closures have a high surface area/depth ratio, multilevel or stack molds are used to maximize unit output per cycle. Many bottle and jar closures are injection molded from polypropylene. High impact polystyrene and polypropylene are both injection-molded for refrigerated dairy product and specialty food cup packaging.

Insert injection molding is used to manufacture snap closures for yogurt and ice cream cups and tubs. In insert injection molding, a die-cut printed paperboard or other flat material is placed in the mold. The plastic is extruded around the insert to form a precision skeletal structure.

Injection-molded articles can be decorated by in-mold labeling or by post-mold decoration. In the former method, printed film is inserted into the mold cavity before injection. The plastic forms an intimate contact with the graphic material. Postmold decoration includes hot stamping, dry offset printing, and decal printing.

Injection molding is used for the preparation of polyester preforms for blow molding into bottles, eg, carbonated beverages or salad dressing, and jars, eg, peanut butter. Resins such as polyester with narrow melt-temperature ranges require sequential fabrication steps. A blow-molded parison is injected at melt temperature and gently reheated to softening below melt temperature for stretching or blowing into a bottle or jar.

To enhance water vapor or gas barrier properties, layers of different plastics may be injected together or sequentially. Multilayer injection-molded pieces may be prepared as packaging or for blowing into bottle or jar shapes.

Sheet Extrusion and Thermoforming. Sheet for thermoforming and analogous operations is usually formed by extruding the melt through a slot die onto a set of polished chill rolls. The sheet is usually ~150 centimeters (~59 inches) wide. After rapid cooling, the web is coiled or cut into sheets. Polystyrene, PVC, polyethylene, polypropylene, and filled polypropylene are prepared in sheet form by cast extrusion.

Thermoforming involves plastic sheets, thicker than 0.25 mm (0.01 in), followed by forming a reheated sheet in an openface mold by pressure, vacuum, or both sequentially or simultaneously. Sheet of <0.25 mm (<0.01 in) thick is often thermoformed in-line, and filled and sealed with contents, such as processed meats, cheeses, and pastas.

Thermoformable sheet may be mono- or multilayer with the latter produced by lamination or coextrusion, or both. Multilayers are employed to incorporate high oxygen-barrier materials between structural or high water vapor barrier plastics. Both ethylene vinyl alcohol copolymers and poly(vinylidene chloride) (less often) are used as high oxygen-barrier interior layers with polystyrene or polypropylene as the structural layers, and polyolefin on the exterior for sealing to produce expanded plastic, gas may be introduced by blending thermally reactive chemicals which release gas into the resin at the extruder. Extrusion heat initiates the reaction to release gas and expand the melt. Alternatively, gas may be injected into the plastic sheet as it is extruded.

Steam-Chest Expansion. In steam-chest expansion the resin beads in which gas is already present are poured into molds into which steam is injected. The steam increases the temperature close to the melting point and expands within the structure to create beads with food cushioning and insulating properties. Expanded polystyrene is widely used in this process for thermal insulation of frozen food packaging.

Three-Dimensional Packaging.

Thermoforming. Is the most common method of fabricating sheet into three-dimensional packaging. In conventional thermoforming, the sheet is heated to its softening point or just below the melting temperature. The softened plastic is forced by differential air pressure into an open-top mold to assume the shape of the female mold. The mold is chilled and the plastic sheet solidifies and is then removed from the mold.

The mold is usually prepared with orifices to permit air trapped between the sheet and the mold to escape and ensure uniform, close contact of the plastic with the mold surface. By clamping the sheet beyond the perimeter of the piece, plastic may be drawn from the peripheral areas into the mold, ensuring uniformity. Both pressure and vacuum are employed to force the softened plastic sheet into the mold.

Thermoforming is used for gauges above 6 mm (0.24 in) in some nonpackaging applications; for packaging applications gauges are between 0.6 and 2.5 mm (0.02 and 0.10 in). The material is stretched during formation, and so the greater the depth of draw, the higher must be the

gauge of the original sheet. Depth of draw, defined as the ratio of piece height to cross-sectional surface area, is a measure of the ability to form deep articles. Although deep-drawn pieces are feasible, thermoforming is best suited to shallow profiles of up to 7.5 cm (3 inches); deeper draws often result in thin side walls. Any fully or partially tapered shape with an opening equal to or larger than the body can be made. In commercial practice, packaging is produced from continuous web on intermittent-motion thermoforming–die-cut machines. The web edge is clamped and conveyed into a heating box. If a plastic with a narrow softening temperature is used, heating is carefully controlled from top and bottom. The heated web is conveyed to the forming section, where pressure or vacuum force the softened web into the mold. The mold opens and the web is conveyed to a die-cutting station.

The narrow softening temperature range and structural properties of polypropylene led to the development of special controlled-temperature forming processes called solid-phase pressure forming (SPPF). The polypropylene sheet temperature is brought to above the softening temperature, but well below the melting point and subjected to forming pressures three to five times those used for fabrication of polystyrene.

Conventional thermoforming of polystyrene is a widely used technique for making packages for dairy products and for disposable cups and trays. In recent years, injection molded polypropylene has competed with thermoformed polystyrene for dairy cups.

Thermoforming may be integrated with filling and sealing on thermoform/fill/seal machines operated in-plant by food packagers. The base web is gripped and moved through heating and forming operations. The open-top pieces are filled and a second web of material is heat sealed to the flange of the base by heated pressure bars. Cutting may take place during or after sealing.

Retortable plastic cans and trays, designed for low acid foods, may be hermetically sealed and thermally sterilized up to 125 °C (257 °F). High oxygen-barrier properties are usually required. These cans or trays are constructed of five-layer coextrusions of PVDC or ethylene–vinyl alcohol (EVOH) as the gas barrier layers and polypropylene, with extrudable adhesive layers. The trays must be thermoformed and aged before filling and sealing to minimize heat-seal distortion due to stress, unless melt-to-mold fabrication procedures are employed. Counterpressure and temperature during retorting must be carefully controlled to avoid heat seal distortion.

Melt-to-mold thermoforming overcomes the thermal stresses developed in forming polypropylene sheet. As the plastic is extruded from the slot die and while it is still hot, it is transferred into the mold. To maintain thermal and mass equilibrium, the molds move continuously past the slot from which the melt is discharged and the plastic is formed in the molds. Melt-phase thermoforming has been used to produce monolayer frozen food tubs and wide-mouth snap closures, for fabricating crystallized polyester trays for dual ovenable applications, and for coextruding multilayer structures incorporating EVOH for hot fill, aseptic, and retort packaging of foods.

Blow Molding. In conventional blow molding a single extruder propels the plastic melt through an annular die to form a tubular parison that is delivered into the open mold. The mold closes, pinching off the bottom and gripping the top. An air-blow tube is inserted through the neck opening and pressurized air is blown in to expand the hot, soft plastic to the chilled walls of the mold. Upon setting, the parison drops or is extracted from the mold. Excess flash is mechanically trimmed.

Extrusion blow molding produces narrow-neck bottles from high and low density polyethylene. Bottles with adequate neck finishes are produced. Without good parison control, bottle wall thickness varies, ie, areas of greater diameter have thinner walls, whereas base, shoulder, and neck areas have thicker walls. These bottles may be fabricated with hollow handles. They may be decorated by in-molding labeling, with decals, by screen printing, or by hot stamp or postmold labeling.

Conventional extrusion or coextrusion may be performed on vertical or horizontal rotary or shuttle mold configurations. In shuttle blow molding the extruder and die are in fixed horizontal and vertical position; two or more molds shuttle into and out of position beneath the die. By reciprocating in two planes, the mold may remove a parison and permit the extruder to function continuously.

Horizontal rotary machines employ multiple molds in a horizontal plane on a rotary turret. As each mold approaches the extruder die exit, it opens to accept the parison and then closes. The parison is then blown into the bottle shape. The extruder must extrude on an intermittent basis or be intermittently withdrawn to provide a parison for each passing mold.

Vertical rotary molds also employ multiple molds on a turret but rotate in a vertical plane. As each mold reaches the die exit, it grasps the parison and closes. Because of the vertical spacing between molds, intermittent extruder action is not required. Vertical wheels are used commercially for high volume applications.

Because high oxygen-barrier plastics are generally incompatible with other thermoplastics, extrudable adhesives must be extruded between the layers of multiplayer structures. Scrap can be included within the multilayer structure, provided an extrudable adhesive is incorporated.

Incorporating EVOH as high oxygen barrier with polypropylene is used for packaging tomato catsup, barbecue sauce, mayonnaise, pickle relish, syrups, prepared foods, and other foods. Bottles fabricated from internal and external layers of polypropylene contain EVOH as the principal high oxygen-barrier material.

Extrusion blow molding of polypropylene is not easy because of its narrow softening-to-melt temperature range. Bottle orientation enhances structural strength. For monolayer polypropylene bottles, a two-stage process produces a continuous extrusion of pipe that is cut into fixed parison lengths. The parisons are reheated and stretched longitudinally before circumferential blowing. Impact resistance, gloss clarity, and stiffness are improved, but barrier properties are not.

Plastic with a very narrow melt temperature range, such as polyester and polypropylene are formed into bottles by injection stretch blow molding. A test tube shape is first formed by injection. This preform is transferred to the blow-molding machine and slowly heated to uniform temperature. The heated parison is placed in the blow mold in which it is stretched to induce vertical orientation and blown to shape. Blowing induces horizontal orientation to provide circumferential or hoop structural strength. Stretching and blowing reduce wall thickness, whereas orientation improves structural strength.

Injection stretch-blow molding may be performed on a single one-stage machine in sequence or on two independent sequential two-stage machines. The PET carbonated beverage bottles are usually produced by injection stretch blow molding.

Multilayer injection stretch blow molding has been commercialized for both narrow neck and wide-mouth containers. The basic form is fabricated by injecting multiple layers, such as polypropylene and EVOH plus tie layers, and blowing the parison. Several high oxygen-barrier cans with plastic bodies and ends intended for metal end double seam closing have been introduced. Cans containing polypropylene and EVOH are retorted after filling to resist retort temperatures up to 125 °C (257 °F).

Heat-Stabilized Molding. Recognition of the merits of hot filling foods into plastic packaging, followed by sealing and cooling, has led to a need for high oxygen-barrier plastic containers capable of resisting temperatures up to 85–90 °C (185–194 °F) for brief periods. Resistance to internal vacuum can be achieved by structural design. Plastics with distortion temperatures > 100 °C(> 212 °F), eg, polypropylene and high density polyethylene, may be filled with hot liquid without fear of thermal distortion, although vacuum collapse is an issue. Polyester requires physical modification to resist heat, drying to remove water, partial crystallization, and heat stabilization. In heat stabilization, the container is molded and briefly secured in the mold while at elevated temperature rather than chilled immediately. The crystalline structure of the material is thereby altered to resist moderately elevated temperatures. This technique is employed to produce PET bottles for filling with hot liquids.

Blow-Mold-Fill-Seal System. Some blow-molded bottles are produced in blow-mold–fill–seal operations engineered for aseptic packaging. On blow-mold–fill–seal machines the parison is extruded through an annular die into a sterile space containing sterile molds. The parison is blown with sterile air and immediately filled with cooled product. After filling, the bottle is closed by heat-seal fusion within the mold and removed from mold and sterile chamber through a small opening protected against contamination by the pressure of sterile air.

This method is slow because of the multiple operations on a shuttle machine. The heat of extrusion sterilizes the bottle, which is not readily achieved after molding. Blow-mold–fill–seal systems are used commercially for beverages and for pharmaceutical packaging.

FOOD PROCESSING. Food processing operations can be grouped into three categories: preparation, assembly, and preservation of foods. Preparation processes are used to convert raw plant or animal tissue into edible ingredients. This may include separation of inedible and hazardous components, extraction or concentration of nutrients, flavors, colors, and other useful components, and removal of water. Assembly processes are used to combine and form ingredients into consumer products. Preservation processes are used to prevent the spoilage of foods. Five sources of food spoilage must be addressed in order to deliver fresh, safe foods and ingredients: microbial contamination, including viruses; enzyme activity from enzymes in the food itself and from external enzymes such as from microbial activity; chemical deterioration such as oxidation and nonenzymatic browning; contamination from animals, insects, and parasites; and losses owing to mechanical damage such as bruising. Preservation processes can be used to extend the shelf life of fresh foods, such as produce, or to manufacture products for long-term storage where shelf lives are measured in years. The processing of foods is regulated by federal food laws that cover good manufacturing practices, nutritional content of foods, and food and ingredient standards.

Plants and animals are the primary sources of food. The food processing industry devotes considerable research to the selection and improvement of plants and animals for raw materials. Genetic engineering, as well as conventional breeding methods, are being used to improve the yield, color, flavor, texture, nutrient content, and resistance to diseases, insect loss, and climatic stress. However, product quality can vary owing to weather, soil, growing practices, harvest methods, and postharvest handling. Thus food processing unit operations must be designed to accept raw materials having a wide range of qualities. In addition, provision often must be made for profitable use of by-products and waste streams. See also **Genetic Engineering**.

Food processing operations are usually regulated and mandated by national and international laws, regulations, and standards that define nutritional requirements and the use of certain ingredients, process conditions, and even the composition of some products. Food safety and toxicology regulations include standards for toxic and carcinogenic substances in foods, pathogenic microbes, and physical hazards. Chemical hazards include heavy metals, carcinogens such as aflatoxins and nitrosamines, pesticides and herbicides, and other natural toxicants such as solanin and gossypol. Microbial hazards include *Clostridium botulinum Listeria monocytogenes*, and *Salmonella* sp. Physical hazards include extraneous material such as metal, wood, pits, glass, insect fragments, and rodent hair. Food regulations are covered in the Federal Code of Regulations.

Process Optimization

A number of food processing unit operations, such as distillation, filtration, and crystallization, are common to the chemical process industry. Mechanical operations such as size reduction, materials handling, and mixing are also similar to those used in chemical processing. Food processing operations can be optimized according to the principles used for other chemical processes if the composition, thermophysical properties, and structure of the food is known. However, the complex chemical composition and physical structures of most foods can make process optimization difficult. Moreover, the quality of a processed product may depend more on consumer sensory responses than on measurable chemical or physical attributes.

Food process optimization measurements may link a single chemical compound such as a vitamin, or a physical change such as viscosity, to process conditions and to consumer acceptance. Retention levels of ascorbic acid [CAS: 50-81-7], $C_6H_8O_6$, or thiamine can often be used as an indicator of process conditions.

Theoretical Basis. Food preservation theory has yielded mathematical models for predicting the heating times and temperatures needed to produce foods free of pathogenic or spoilage microbes. Mild heat treatments used to inactivate viruses, vegetative pathogenic bacteria such as *Salmonella* sp., and certain yeasts and molds, are referred to as pasteurization operations. Milk pasteurization treatments at 61.67 °C (143.01 °F) for 30 min or 71.67 °C (161.01 °F) for 15 s are examples. See also **Yeasts and Molds**.

Spore-forming bacteria are among the most heat-resistant organisms known. For example, a population of 10,000 spores of *Bacillus stearothermophilus* must be held at 121 °C (250 °F) for ∼16 min to ensure complete inactivation. These spores are found as contaminants in many raw plant and animal ingredients and must be inactivated or prevented from germinating to prevent the spoilage of heat preserved foods. The spore-forming bacteria of greatest public health concern are the several types of *C. botulinum*. Upon germination, *C. botulinum* releases a highly toxic, cyclic, polypeptide, which is among the most potent human toxins known, based on molecular weight. Research since the early 1920s has been directed toward the development of mathematical models to predict the rate of heat inactivation of *C. botulinum* spores as a function of heating time and temperature, and the composition of the suspending media. Heat inactivation rates can be influenced by pH, water activity, salts such as nitrates, nitrites, and sodium chloride, and other chemicals. The polypeptide toxin itself can be inactivated by heating at 100 °C (212 °F) for 10 min. See also **Foodborne Diseases**.

Spore germination can be inhibited by antibiotic substances produced by several types of lactic acid-producing bacteria. These substances, called bacteriosins, are finding increased use in preventing the growth

of gram-positive bacteria. Nisin [CAS: 1414-45-5], $C_{143}H_{230}N_{42}O_{37}S_7$, a particularly effective bacteriosin against *C. botulinum*, is allowed in processed cheese food. Wider use is expected in the United States as nisin has already been approved for use in many foods in other countries.

Two other broad areas of food preservation have been studied with the objective of developing predictive models. Enzyme inactivation by heat has been subjected to mathematical modeling in a manner similar to microbial inactivation. Chemical deterioration mechanisms have been studied to allow the prediction of shelf life, particularly the shelf life of foods susceptible to nonenzymatic browning and lipid oxidation.

Water Activity. The rates of chemical reactions as well as microbial and enzyme activities related to food deterioration have been linked to the activity of water in food. Water activity, at any selected temperature and moisture content can be measured by determining the equilibrium relative humidity surrounding the food. Thus water activity is different from, but related to the moisture content of the food as measured by standard moisture tests. A plot of the relation of moisture content and water activity at any temperature is called a moisture-sorption isotherm. See also **Water**.

At very low concentrations of water, or in foods held below the freezing point of water, physical conditions may be such that the available water may not be free to react. Under these conditions, the water may be physically immobilized as a glassy or plastic material or it may be bound to proteins and carbohydrates. The water may diffuse with difficulty and thus may inhibit the diffusion of solutes. Changes in the structure of carbohydrates and proteins from amorphous to crystalline forms, or the reverse, which result from water migration or diffusion, may take place only very slowly. See also **Carbohydrates**; and **Protein**.

When water activity is low, foods behave more like rubbery polymers than crystalline structures having defined domains of carbohydrates, lipids, or proteins. Water may be trapped in these rubbery structures and be more or less active than predicted from equilibrium measurements. As foods change temperature the mobility of the water may change. A plot of chemical activity vs temperature yields a curve having distinct discontinuities indicating phase changes in the structure of the food system and possible release or immobilization of water. An important phase change is that from a rubbery or glassy structure to a more crystalline one defined by the glassy point transition temperature. The glassy point transition temperature of a frozen food may be important for long-term storage stability. Similarly, for baked or dried foods stored at room temperature, the glassy point transition temperature may indicate a temperature at which staling, loss of softness, or the development of an undesirable texture may take place. Glassy point transition temperatures and the non-equilibrium analysis of food structures have been studied.

Preservation of Foods

Preservation operations to reduce or eliminate food spoilage can be grouped into five categories: heat treatments; storage near or below the freezing point of water; dehydration and control of water activity; chemical preservation; and use of mechanical operations such as washing, peeling, filtration, centrifugation, grinding, ultrahigh hydrostatic pressure, and most importantly, packaging. Most food preservation technologies use two or more preservation operations because virtually all processed foods are packaged.

The extension of the useful storage life of plant and animal products beyond a few days at room temperature presents a series of complex biochemical, physical, microbial, and economic challenges. Respiratory enzyme systems and other enzymes in these foods continue to function. Their reaction products can cause off-flavors, darkening, and softening. Microbes contaminating the surface of plants or animals can grow in cell exudates produced by bruises, peeling, or size reduction. Fresh plant and animal tissue can be contaminated by odors, dust, insects, rodents, and microbes. Packaging must be used to protect the food from these contaminants. See also **Freeze-Concentrating**; and **Freeze-Drying**.

Short-Term Storage

Controlled Atmosphere. The composition of the gas atmosphere surrounding certain respiring fruits and vegetables and meat products can influence their rate of quality loss. For example, an atmosphere having only a few percent of oxygen, 12% carbon dioxide, and the remainder nitrogen, can prolong the useful storage life of selected varieties of apples in refrigerated storage. Using this atmosphere, a shelf-life extension from 3–9 or 10 months is possible. Studies using refrigerated meat and poultry products have shown that gas mixtures containing 50% oxygen, several percent carbon dioxide, and the remainder nitrogen can extend the useful shelf-life of these products from days to weeks. In this case, the oxygen inhibits the growth of anaerobic spoilage bacteria under refrigerated conditions.

Controlled atmosphere storage, when used for blemish-free products, is an effective preservation method for clean, intact foods, such as fresh apples and pears. Packaging has been developed to take advantage of the respiration processes taking place in fresh foods. Packaged produce can metabolize oxygen and release carbon dioxide. Packaging materials can be designed to allow diffusion of oxygen from the atmosphere into the package and carbon dioxide to the atmosphere to maintain a desirable ratio of these gases in the package. A ratio can be obtained that is sufficient to reduce the respiration rate of the food and inhibit the growth of aerobic microbes. Chemical gas scavengers can be included in the package to remove undesirable metabolic gases such as ethylene which can influence the rate and course of respiration.

Refrigeration. Foods contaminated with microbes from various unit operations may require additional preservation to ensure a useful shelf life. Refrigeration slows the growth of spoilage microbes. The effectiveness of refrigeration can be improved by combining storage just above freezing with ionizing radiation or chemical preservatives, eg, food acids, sodium benzoate, [CAS: 532-32-1] and nisin; treatment with ultrahigh [$\sim$300–700 MPa (44,000–103,000 psi)] pressure; and for liquid foods, filtration or centrifugation to remove microbes. Holding pork at $-15\,^{\circ}C$ ($5\,^{\circ}F$) for up to 30 days can be used to inactivate *Trichina spirales*, the cause of trichinosis. Raw seafood can be frozen to inactivate parasites.

Vacuum packaging has been effective in extending the shelf-life of refrigerated processed meats. The use of a combination of several preservation steps to inhibit spoilage and induce minimal changes in the quality of the fresh food has been likened to establishing a series of hurdles. In some cases a very mild heat treatment, such as holding at $60\,^{\circ}C$ ($140\,^{\circ}F$) for several minutes, helps reduce microbial and possibly insect contamination without extensive damage to the quality of fresh plant or animal tissue.

Heat Treatment. Shellfish taken from sewage-contaminated waters and containing pathogenic virus can be made safe by thorough cooking. Foods contaminated with large numbers of pathogenic microbes, or containing heat-labile toxins, however, are generally unsuitable for human consumption even if heat could be used to render these foods safe. Foods containing heat-stable microbial toxins, but otherwise free of microbes, are particularly hazardous because these may have no detectable signs of spoilage. Canned mushrooms have been implicated in staphylococcal food poisoning. Staphylococcal enterotoxin may lose only 90% of its toxicity by heating 19 min at $121\,^{\circ}C$ ($250\,^{\circ}F$).

Preservatives. Bakery products represent an important category of minimally processed foods. Bread and other yeast and chemically leavened baked products can lose their fresh quality characteristics within 24 h at room temperature owing to chemical changes brought about by water migration and starch crystallization. This quality loss, evidenced by staling, represents a complex set of changes among the starch, protein, water, and lipid components of the product. Additives such as sodium stearoyl lactylate can inhibit staling in bread for up to several weeks. The potential for the growth of microbes, such as molds, which can tolerate low water activity conditions, can create the need for a hurdle preservation strategy for extending the shelf-life of fresh bread. Propionates as mold inhibitors or packaging in an oxygen-free modified atmosphere can prevent mold growth. See also **Bakery Processes (Yeast-Raised Products)**.

Long-Term Storage. Inactivation of microbes and enzymes in foods and food ingredients is necessary to ensure a long useful packaged shelf-life. This can be achieved by using one or more preservation operations such as applying heat; using storage temperatures below $-18\,^{\circ}C$ ($-0.4\,^{\circ}F$); drying to water activities <0.65, ie, an equilibrium relative humidity surrounding the product $<65\%$; and by adding chemical preservatives such as organic acids (acetic or lactic) or table salt. Generally, heat is used to inactivate enzyme activity prior to other preservation treatments. A mild heat treatment to inactivate enzymes in foods prior to freezing, drying, or chemical preservation is known as blanching.

Food processing firms producing heat-preserved, frozen, dehydrated, or chemically preserved foods may be classified by their finished products. Companies may be further grouped based on whether they process raw materials into ingredients, such as in poultry and meat processing plants,

or whether they take these ingredients and convert them to ready-to-eat, convenience consumer products.

Thermal Preservation Technology. The heat preservation of foods can be accomplished by various combinations of heating times and temperatures depending on the number and type of heat-resistant spores present, the composition of the food, and the physical characteristics of the food and package. Physical characteristics of the food such as viscosity, size of particles, size of the package, and starting temperature influence the rate of heat penetration into the slowest heating point in the package.

The inactivation of heat-resistant spores appears to follow first-order kinetics. Thus if the rate of inactivation of a spore population is known at several temperatures, and the rate of heating of the slowest point in a package can be determined or calculated from heat-transfer principles, then the time needed to sterilize the package can be calculated for any external heating condition. Mathematical formulas for calculating times and temperatures needed to heat foods in cylindrical containers to achieve any desired level of microbial inactivation are discussed in [Teixeira A., Ref.]. Computer programs are available that can be used in an interactive mode to monitor steam retort operations in real time to adjust for process deviations. Process deviations are changes in the operating conditions of the retort, such as retort steam pressure, or initial conditions of the product to be heat sterilized, such as product temperature. These are changes from values established with the Food and Drug Administration (FDA) as necessary to produce thermally processed foods free of *C. botulinum*.

The establishment of safe thermal processes for preserving food in hermetically sealed containers depends on the slowest heating volume of the container. Heat-treated foods are called commercially sterile. Small numbers of viable, very heat-resistant thermophylic, spoilage causing, spores may be present even after heat treatment. Thermophylic spores do not germinate at normal storage temperatures.

Chemical changes in foods resulting from heating, such as the loss of pigments, flavors, and vitamins, can also be approximated by first-order kinetics. These reaction rates, however, are much less sensitive to temperature change than are the rates of microbial inactivation. The activation energies for chemical changes in foods are often lower by a factor of 5 than the activation energies for the inactivation of spores.

If food can be heated quickly to a temperature of 131 °C (268 °F) a lethality equivalent to 6 min at 121 °C (250 °F) can be accumulated in 36 s. Rapid heating and cooling of liquid foods, such as milk, can be performed in a heat exchanger and is known as high temperature short time processing. HTST processing can yield heat-preserved foods of superior quality because heat induced flavor, color, and nutrient losses are minimized.

Equipment. Equipment and processes for thermal preservation depend on the physical form of the food and its pH. Foods at pH 4.5 or lower often can be sterilized, for commercial purposes, at or near a temperature of 100 °C (212 °F). Commercial sterility for these products means that the product will not spoil owing to microbial growth as long as the pH remains at or <4.5. Hydrogen ion activity inhibits the germination of *C. botulinum* spores as well as the spores of most other heat-resistant microbes. The spores of *Bacillus coagulans* are an important exception. This microbe is found in tomato products, and these products are often adjusted to a pH 4.0 or lower, or given an additional heat treatment to insure sterility. See also **Hydrogen Ion Activity**.

Acid foods generally require the simplest equipment for heat preservation. The food can be heated in the range of 100 °C (212 °F) and filled hot into suitable containers. The containers are sealed, inverted to sterilize the closure, held at the filling temperature for a short time to ensure that the package is thoroughly heated, and then cooled. Tomato sauces, jellies, fruits, fruit juices, and pickles are routinely preserved in this fashion.

Low acid foods, those having a pH >4.5, require sterilization at temperatures >100 °C (>212 °F), and thus require treatment in pressure vessels. Heat preservation processes >100 °C (>212 °F) can be carried out in batch or continuous heat-exchange equipment. Batch retorts are simple pressure vessels in which the packaged food can be exposed to saturated steam, water and air over pressure, water sprays and air over pressure, or mixtures of air and steam. See also **Steam**. Microwave energy can be used to heat suitable plastic or glass packages. Small cans serve as their own individual pressure vessels and thus can be heated by direct flames, fluidized beds, or electrical resistance heating. Packages containing fluid foods or slurries with particles can be agitated to increase internal heat transfer. Rigid cans may be filled with particulate foods under very high vacuum with very little liquid to promote the formation of a steam atmosphere inside the package during heat treatment. This atmosphere greatly increases internal heat transfer. Low acid foods can be packaged in chambers pressurized above one atmosphere so that water boils at >121 °C (>250 °F). Under these conditions the heated food can be filled directly in an appropriate package, held for a short time to sterilize the package, and then cooled. Workers and all materials must pass through air locks on entering and leaving. This process has been designed as Flash 18 by its developers.

An interesting application of high pressure to heat sterilization used the phenomenon of compressing heating and expansion cooling of water to achieve almost instantaneous heating and cooling of foods packed in plastic packages. Water shows a 3 °C (37 °F) increase in temperature for each 100 MPa of compression. Thus compression of moist food with an initial temperature of 98 °C (208 °F) to 600 MPa can increase the temperature of the food to 116 °C (241 °F). Decompression reduces the food temperature back to 98 °C (208 °F). An appropriately sized water compression system can achieve the pressure of 600 MPa in a process pressure vessel in 1–2 min. Decompression requires seconds.

Research has shown that combinations of temperatures >100 °C (>212 °F) with pressure above 600 MPa can sterilize foods, with holding times at pressure of several minutes. This translates to complete sterilization process times of <5 min for any type of low acid packaged food, regardless of piece or packages size. The concept is under development as a practical food sterilization technology.

Batch process equipment has the advantages of low capital investment and flexibility. There is little restriction on the form or size of the package and length of heat treatment. Systems are available having fully automated process cycle controls and materials handling for ease of loading and unloading. Disadvantages of batch equipment are slow cycle times, because the system must be heated and cooled for each process cycle, and higher energy and labor costs. Materials handling costs are also higher. In general, batch heat process systems are useful in food processing operations that produce a mix of products, in a number of package sizes, with a limited numbers of cases required for any product style.

Continuous heat processing equipment can take the form of heat exchangers for pumped foods, or a materials handling system that automatically introduces individual packages into a sealed steam pressure chamber. Equipment for handling individual packages can use either a mechanical valve system, such as rotating pockets, or hydrostatic legs of sufficient height to balance the internal steam pressure of the system. A hydrostatic cooker operating at 121 °C (250 °F) with a gauge pressure of 0.1 MPa (14.5 psi) typically uses 20 meter (66 feet) tall hydrostatic inlet and outlet legs. This height is needed to provide a safety factor for possible changes in water level during operation.

Packages are placed on carriers affixed to an endless chain, which travels through the system. Package cooling takes place in the decompression leg. Package treatment rates of 1000 containers per minute are possible. Treatment rates of several hundred packages per min are possible using mechanical valve systems.

Foods continuously heat sterilized and cooled in heat exchangers must be filled aseptically in presterilized packages. Ohmic, microwave, and induction heating allow particulate foods to be heated more rapidly and uniformly than conduction heating by conventional or wiped-surface heat-exchanger technology. The filling of sterilized and cooled product into presterilized packages, under sterile conditions, is referred to as aseptic processing and has several advantages over inpackage sterilization. One advantage is that heating and cooling for sterilization is independent of package size and package composition. Packages ranging from a few cubic centimeters to the size of bulk tank cars can be prepared with equal quality. Products are filled at room temperature. Thus packages can be constructed from plastics having a relatively low softening temperature. These packages can have lower costs and greatly reduced permeability because heat-resistant polymers are not needed. Additionally, a wider range of structures is possible.

Aseptic filling systems can accept a wide range of packages including metal cans and covers sterilized by superheated steam; paper, foil, and plastic laminates sterilized by hot hydrogen peroxide; ionizing radiation sterilized bags; and a variety of plastic and metal containers capable of being sterilized by high pressure steam. A novel aseptic filling system designed for acid foods, such as applesauce and fruit juices, uses hot, food-grade, organic or inorganic acid to produce commercially sterile packages

as they enter the sterile filling area. Aseptic filling machines can use filtered air or nitrogen under a slight positive pressure to prevent the entrance of microbes into the sterile filling area where the sterile product is filled and sealed in presterilized packages. A nitrogen or other inert atmosphere is preferred to keep oxygen away from the product when the package is sealed.

Aseptic processing systems have found wide use for packing juices and dairy products for the retail market and for the bulk preservation of tomato paste and fruit slices for use as ingredients.

Freezing Preservation. The rate of loss of color, flavor, texture, and nutrients, the growth of microbes, and the activity of enzymes and other life forms are all functions of temperature. Thus lower storage temperatures prolong the useful life of foods. Below 0 °C (32 °F), the free water in foods starts to form ice crystals. Ice crystal formation is a function of moisture content, solute composition, and storage temperature fluctuation. Supercooling can occur during the freezing process, but it is a transient phenomenon. Foods having high concentrations of solutes can behave as glassy materials in which water may exist in a noncrystalline state at freezing temperatures owing to inhibited diffusion and high soluble solids content.

Ice formation is both beneficial and detrimental. Benefits, which include the strengthening of food structures and the removal of free moisture, are often outweighed by deleterious effects that ice crystal formation may have on plant cell walls in fruits and vegetable products preserved by freezing. Ice crystal formation can result in partial dehydration of the tissue surrounding the ice crystal and the freeze concentration of potential reactants. Ice crystals mechanically disrupt cell structures and increase the concentration of cell electrolytes, which can result in the chemical denaturation of proteins. Other quality losses can also occur [Fennema, Powrie and Marth Ref.].

Equipment for food freezing is designed to maximize the rate at which foods are cooled to −18 °C (−0.4 °F) to ensure as brief a time as possible in the temperature zone of maximum ice crystal formation. This rapid cooling favors the formation of small ice crystals, which minimize the disruption of cells and may reduce the effects of solute concentration damage. Rapid freezing requires equipment that can deliver large temperature differences and/or high heat-transfer rates. Foods, not packaged, exposed to large temperature differences, and high heat-transfer rates can under go significant moisture loss, as heat and mass transfer coefficients are linked. Freezing equipment should be designed to minimize this moisture loss. Some approaches are outlined in the section in freezing equipment.

Many formulated foods and certain animal products tolerate freezing and thawing well because their structures can accommodate ice crystallization, movement of water, and related changes in solute concentrations. Starches can be modified for freeze–thaw stability against gel breakdown through several freeze–thaw cycles. By contrast, most fruits and vegetables lose significant structural quality on freezing and during storage because their rigid cell structures fail to accommodate to ice crystal formation. Frozen food storage equipment must be designed to minimize temperature fluctuations. It is not practical to store commercial frozen foods at temperatures low enough to ensure complete conversion of all water to ice. Commercial frozen food storage temperatures (−18 to −24 °C (−0.4 to −11 °F) represent an economic balance between storage costs measured in time, energy, and capital investment, and desired shelf-life and product quality.

Freezing can also disrupt tissue structures and allow cell contents to become mixed so that undesirable enzyme–substrate reactions can take place at significant rates even at storage temperatures of −18 °C. These reactions can generate off-flavors, reduce nutrient concentrations, and cause changes in the structure and appearance of foods. The amount of free liquid or drip found after a freeze–thaw cycle is a good indication of structural damage. Heat treatment (blanching) prior to freezing is used to eliminate enzyme activity. Most enzymes responsible for quality loss in plant materials can be inactivated by exposure to a temperature of 100 °C (212 °F) for 1–5 min. Enzymes in heat-sensitive fruits often can be inhibited using sulfur dioxide, sucrose, or combinations of citric acid, table salt, and ascorbic acid, preceded by vacuum removal of air if heat is not used. Specific, nontoxic, enzyme inhibitors have been described in the literature.

Most frozen foods have a useful storage life of 1 year at −18 °C. However, foods high in fat such as sausage products may become rancid after 2 weeks in frozen storage if not protected from oxygen by special packaging and antioxidants. The time–temperature tolerances of various frozen foods are discussed in [Van Arsdel, Copley and Olson Ref.]. Moisture migration and loss of moisture through packaging materials or defective seals can occur in frozen foods during storage. The process is similar to freeze–drying and is accelerated if the storage temperature is not constant. The heat-transfer surfaces used to maintain the storage temperature of a frozen storage room must be at a lower temperature than the storage area and frozen foods must be protected by moisture-proof packaging. Storage under varying temperature conditions favors the migration of water in the food from areas of high to areas of low concentration. In addition, foods susceptible to oxidative deterioration must be protected from air by hermetically sealed containers, by coating with an oxygen impermeable coating, or by incorporating an antioxidant in the product. Water glazes have been used to protect fish during frozen storage. Edible barriers are being evaluated to limit the rate of moisture migration [Torres Ref.].

Equipment. Food freezing equipment can be classified by the method and medium of heat transfer used. High velocity air is the most common medium used for direct contact freezing of nonpackaged foods. Typically, foods are loaded on a continuous mesh or perforated belt and passed through air moving upward at 5 m/s at temperatures as low as −40 °C (−40 °F). The air is recycled through cooling coils and fans located next to the conveyor and returned through the conveyor. Because cold air has a partial water vapor pressure lower than the warm food, evaporation to the extent of several percent of the weight of the food can occur from the surface. This water vapor condenses on the air-cooling coils, making periodic defrosting necessary. Whereas air is a convenient and safe heat-transfer medium for food freezing, it has several drawbacks including its low heat capacity and poor heat-transfer characteristics. Rapid freezing requires high air velocities and low operating temperatures. For these and other reasons many foods are frozen in equipment using conduction or liquid heat-transfer methods. Capital and energy savings, reduced moisture loss, and elimination of defrosting are some advantages of these methods.

Liquid heat-transfer media for immersion freezing include solutions of edible salts, sugars, alcohols, and esters. These heat-transfer agents offer high heat-transfer rates, reduced pumping costs, and allow operating at higher refrigerant temperatures. Not all foods are suitable for direct immersion in these freezing media. However, irregularly shaped foods such as whole turkeys can be shrink wrapped in plastic and thus can be adapted to immersion freezing.

Conduction freezing between chilled plates is a very cost-effective method of heat removal for products that can be packaged in such geometry so as to fit between refrigerated plates. Packages having a regular geometry, such as a semiinfinite slab, can be loaded automatically between platens through which a refrigerant is circulated. The platens are stacked to provide a large product-holding capacity and thus sufficient contact time to ensure complete freezing. As unfrozen packages are introduced, frozen packages are removed in a continuous fashion. Good conduction heat-transfer conditions are achieved by maintaining pressure on the stack of platens to ensure good contact between the package and heat exchanger surfaces.

Cryogenic freezing equipment uses liquid nitrogen or carbon dioxide snow. These units have the advantage of portability and simplicity and can produce extremely fast freezing rates. The refrigerant can be sprayed directly on the product to ensure rapid heat transfer. Cryogenic freezing produces very high quality products and ensures that little product weight loss occurs. This is important for high unit value foods and ingredients such as meat, poultry, bakery, and seafood products. See also **Cryogenics**.

The quality of a frozen food may be determined more by the temperature at which it is stored than by the method or rate of freezing. Storage temperatures may fluctuate as products move from manufacturing through distribution channels to the consumer's home freezer. The useful shelf-life of a frozen food may be severely limited by exposure to storage temperatures above −18 °C (−0.4 °F), even for a few hours.

Dehydration Processing. Dehydration is one of the oldest means of preserving food. Microbes generally do not grow below a minimum water activity of 0.65. Water activity is defined as the equilibrium relative humidity surrounding food in a sealed container at a given temperature, ie, no microbes can grow at a water activity <65% relative humidity at storage temperatures in the range of 0–40 °C (32–104 °F).

Each food or food ingredient shows a characteristic equilibrium relative humidity at a given moisture content and temperature. Thus as a food is

dried and its moisture content is reduced from its fresh value, where water activity is generally 1.0, to lower and lower values, the equilibrium water activity of the food decreases as a complex function of residual moisture. The shape of the equilibrium relative humidity–moisture content curve is set by the chemistry of the food. Foods high in fructose, eg, bind water and thus show lower water activities at high moisture contents. Dried prunes and raisins are examples. Drying can be terminated at any desired moisture content and hence any water activity.

Foods dried to water activities in the range of 0.65–0.85 are often referred to as intermediate moisture foods. These partially dried foods tend to be soft and rehydrate easily. The remaining water acts as a plasticizer. Because molds and yeast may be able to grow in these partially dried products, they must be preserved by heat, vacuum, or modified atmosphere packaging, refrigeration, or chemical means. For example, bakery products can be filled or topped with intermediate moisture content fruit or cheese fillings, which have a microbial stability matching the lower moisture baked pastry portion.

Foods high in sucrose, protein, or starch tend to bind water less firmly and must be dried to a low moisture content to obtain microbial stability. For example, grain and wheat flour can support mold growth at moisture contents >15% (wet basis) and thus are stored at moisture contents <14%. Stored grains and oil seeds must be kept at a water activity <0.65 because certain molds can release aflatoxins as they grow. Aflatoxins are potent carcinogens. See also **Starch**.

Fresh plant and animal tissue when dried to a water activity much <0.97 show irreversible disruption of metabolic processes. However, individual metabolic enzymes may retain activity almost to dryness. Foods are usually heat treated (blanched) prior to drying. Some foods, upon drying, are susceptible to rapid nonenzymatic browning owing to high concentrations of reducing sugars, ascorbic acid, and free amino acids. Dry fruits can be treated with sulfur dioxide to prevent nonenzymatic browning. Products susceptible to oxidation and oxidative rancidity such as potato chips, can be treated with antioxidants and inert gas packed to minimize exposure to oxygen. Low temperature storage can further reduce the rate of chemical deterioration. Dehydrated ingredients must have the same water activity when mixed together in a blended product to prevent undesirable moisture migration from high to low water activity ingredients. See also **Amino Acids**.

Equipment. Continuous hot air driers are used to prepare most of the high quality, dried, piece-form fruits and vegetables produced in the United States. Optimum quality can be achieved by matching the rate of heat input to the food to the rate of moisture release from the food while carefully controlling the product temperature. The bed depth, dry-bulb temperature, relative humidity, air velocity, and direction of air movement through the bed are selected to maintain a wet-bulb temperature, which minimizes product deterioration owing to heat-induced chemical reactions. Typically, continuous belt dryers are staged to provide three or more drying zones into which product is fed to give a very even bed depth. The drying product can be redistributed as a progressively deeper bed in each zone. Each zone is set to operate at a controlled wet- and dry-bulb temperature, up or down air-flow velocity, and bed depth which, optimizes product quality, minimizes energy use, and maximizes product throughput. Excessive heating of the product during any stage of drying reduces product quality; thus food dryers must be designed to provide very uniform drying conditions. The successful operation of a continuous belt drying system depends on establishing a uniform feed rate to the belt to ensure a uniform bed depth. Liquids and pastes are commonly dried in spray, drum, or freeze dryers. Particulate foods can be dried in batch or continuous air-fluidized beds or freeze dryers. Many agricultural commodities are sun-dried when weather conditions at harvest provide low humidity, warm temperatures, and good air circulation. See also **Drying (Process)**.

Rehydration rate and extent of rehydration of a dried food are important quality factors. Instantized dried foods refer to products, which re-hydrate to approximate fresh appearance and eating quality in several minutes in the presence of either hot or cold water. Freeze-dried meats, seafoods, vegetables, and specialty products are particularly useful for instant soups, sauces, meals, and garnishes. Instantized rice, potato, and carrot dice, and other vegetable and cereal products, can be made using puffing guns, centrifugal fluidized beds, or single- or double-screw extruders.

Chemical Preservation. Food additives can enhance the effectiveness of food preservation by heat, refrigeration, and drying methods. The addition of a food-grade acid to a low acid food to shift the pH to a value <4.5 allows heat preservation at a temperature of 100 °C instead of in the range of 121 °C. Antioxidants such as butylated hydroxyanisole [CAS: 25013-16-5] (BHA) can be added to potato chips to reduce the need for expensive oxygen-impermeable flexible packaging. Sulfur dioxide is used in wine and in dry fruit and vegetable products to preserve colors and flavors and prevent nonenzymatic browning. See also **Additives (Food)**; and **Grapes and Wines**.

Food can be preserved by fermentation using selected strains of yeast, lactic acid producing bacteria, or molds. The production of ethanol, lactic and other organic acids, and antimicrobial agents in the food, along with the removal of fermentable sugars, can yield a product having an extended shelf-life. Mild heating of foods, acidified by fermentation and packaged to prevent further contamination, results in a shelf stable product. Cucumber pickles and sauerkraut are examples. The course of the fermentation process can be controlled by the addition of sodium chloride to help provide optimum fermentation conditions for the lactic acid-producing bacteria present on the raw materials at harvest. See also **Fermentation**.

Lactic acid-producing bacteria associated with fermented dairy products have been found to produce antibiotic-like compounds called bacteriocins. Concentrations of these natural antibiotics can be added to refrigerated foods in the form of an extract of the fermentation process to help prevent microbial spoilage. Other natural antibiotics are produced by *Penicillium roqueforti*, the mold associated with Roquefort and blue cheese, and by *Propionibacterium* sp., which produce propionic acid and are associated with Swiss-type cheeses.

Ionizing radiation is considered to be a chemical preservation method and applications must be cleared by the FDA for use, not only on a product-by-product basis, but also on a dose basis. In the United States, up to 100 Gy (10,000 rad) may be used to inhibit potato sprouting, and up to 500 Gy may be used to kill insects and insect eggs in grain products. Fruit, poultry, and other fresh products can be pasteurized at doses up to 10,000 Gy to inactivate pathogenic bacteria, spoilage microbes, insects and larva, and parasites, and to reduce total microbial counts to extend refrigerated shelf-life. Packaging materials, spices, and medical devices can be sterilized at doses up to 60,000 Gy. The theory and applications of ionizing radiation in food preservation are discussed elsewhere [Josephson and Peterson Ref.]. The use of ionizing radiation to preserve a food product requires extensive testing to determine the effect of dose on the flavor and possibly structure of the packaged product. Since the absorbed dose is a function of the thickness of the product, product at the surface of the package may receive more radiation than product in the center.

Foods can be treated with solutions of ozone, chlorine, chlorine dioxide, and other approved agents to reduce surface microbial contamination. The success of the treatment depends on the control of concentration, temperature, exposure time and microbial load.

Other Technologies. Several technologies for the preservation of foods using a minimum of heat are being explored. The application of ultrahigh pressure to the preservation of foods has been commercialized [Hoover, and co-workers]. Ultrahigh hydrostatic pressure is known to inactivate vegetative microbial cells and parasites in foods at a rate proportional to pressure at any temperature. Studies using a wide variety of fresh and processed foods have shown that these foods can be rendered free of vegetative bacteria, parasites, yeasts, and molds by subjecting the foods to hydrostatic pressures in the range of 300–600 MPa (43,000–87,000 psi) for times between 1 min and 1 h, at room temperature. Spores, viruses, and food spoilage enzymes, such as polyphenol oxidase, have been found to be quite resistant to inactivation by pressure at room temperature. However, combinations of pressures and temperatures up to 80–90 °C have been used to inactivate spores and enzymes in low acid foods. Pressure resistant viruses are easily inactivated by heat at relatively low temperatures.

Foods having a pH <4.5 can be made commercially sterile using pressures in the range of 400 MPa (58,000 psi) because the germination of most bacterial spores is inhibited. Yeasts and molds are much more susceptible to inactivation by pressure than are vegetative bacterial cells. Pressure appears to disrupt cell membranes and to denature proteins. Foods preserved by ultrahigh pressure processes must be stored at their intended storage temperature for a time sufficient to determine whether microbes can repair pressure damaged cell structures during storage. Inactivation and regeneration rates of pressure treated microbes are strongly influenced by the chemical composition of the media in which they are held.

Equipment for batch ultrahigh pressure preservation of foods has been adapted from units used in the metal and plastic industry for cold or

warm isostatic pressing at operating pressures to 1000 MPa (145,000 psi). Operating volumes of several hundred liters are possible at these pressures using wire-wound and multiple layer vessels. Batch chambers operating from 300 to 600 MPa (43,000 to 87,000 psi) may be made from multiple shrink fit cylindrical tubes that can be closed at either end using continuous thread, interrupted thread, pin, or yoke closures. It is possible to treat liquid foods in a semicontinuous manner by pumping them into a series of pressure vessels, which fill and discharge automatically. The treated foods must be stored and filled under aseptic conditions into presterilized packages as with heat-treated aseptically filled foods. High pressure is used commercially to shuck and pasteurized shellfish, and to pasteurize guacamole and other avocado products, hams, fruit juices, and specialty foods.

Capacitance discharge has also been investigated as a means to pasteurize or commercially sterilize foods, which can pass between plates sufficiently close together to allow an electric field of ∼25,000 V/cm [Mertens and Knorr Ref.]. The field is established preferably as a square-wave pulse of millisecond duration to avoid heating effects. The strong electrical field appears to disrupt or permeable cell membrane structures. The degree of disruption, and hence microbial inactivation, can be related to the number of pulses to which each element of food is subjected. Cell permeability by capacitance discharge can be used to improve the extraction of secondary metabolites from microbes, plant and animal cells, and hence to increase the yield of mechanically pressed fresh fruit and vegetable juices. Very high intensity pulses of visible light can be used to pasteurize fruit juices using a minimum of heating in a manner that appears to be similar to capacitance discharge.

Computer Integrated Manufacturing, Instrumentation, and Controls

Food processing firms are exploring the use of computer integrated manufacturing. However, the diversity of products, the difficulty of measuring meaningful quality attributes on line, and the batch nature of many processes has tended to slow the application of this technology to food processing. However, thermal processing controls have been developed to the point where time and temperature process deviations can be corrected on line. Freezer, dryer, and vacuum evaporator operating conditions can be controlled and optimized using systems already available to the process industry.

An important aspect of food processing, common with other processing industries, is yield of finished product from starting raw materials for any shift and for specific unit operations. Computer integrated manufacturing can start with the measurement of material flows and build upon this information. Instrumentation for the on line measurement of specific food qualities of importance to the consumer such as food flavor, aroma, texture, and microbial content are under development. These quality factors are monitored using statistical quality assurance procedures using standard sampling plans and control strategies.

DANIEL F. FARKAS (retired), Oregon State University, Eugene, OR

FOOD TOXICANTS, NATURALLY OCCURRING. Toxicants are substances which, upon ingestion, product changes in homeostasis that are threatening to the normal function of the organism. There are substantial differences in the toxicity thresholds of individuals to specific agents. Factors affecting toxicity include body weight, sex, age, general state of health, and the presence of potentiating or inhibitory substances.

Toxic Proteins, Peptides, Amides, and Amino Acids

Nitrogenous compounds are the most frequently implicated natural toxicants in foods. These compounds may be grouped either according to gross manifestations or specific structural characteristics. Accordingly, vitamin-destroying enzymes, hemagglutenins, enzyme inhibitors, and many hepatotoxins, are of protein, peptide, or amino acid composition. Many of the hepatotoxins are also carcinogens.

Enzyme inhibitors of a protein nature are of significant concern because of widespread occurrence. The most common of these affect the pancreatic enzymes, trypsin [CAS: 9002-07-7] and chymotrypsin [CAS: 9004-07-3], and are found in legumes, eg, soybeans, peas, most common beans, blackeyed peas, lupine, and khesari, as well as in egg whites and potatoes. See also **Enzyme Inhibitors**.

Many protein inhibitors cause little nutritional difficulty because these compounds are heat labile under ordinary processing and cooking procedures including microwaving, and significant numbers are water soluble.

Many are found in highest concentrations in the outer portions of plants, e.g., wheat bran; thus normal peeling and milling operations also give some protection. It has been demonstrated that treatment with compounds such as sodium sulfite [CAS: 7757-83-7], ascorbic acid [CAS: 50-81-7], and cupric sulfate [CAS: 7758-98-7], as well as fermentation with *Rhizopus oligosporus*, such as in the production of tempeh, is also an effective means of reducing trypsin inhibitor activity in both fresh and hardened common beans.

Reports of specific amino acid toxicities from normal eating patterns are rare. Although all amino acids except alanine [CAS: 56-41-7] have been shown to be toxic, the probability of intoxication is very remote. Humans seem able to tolerate all amino acids in excess of 10 times the recommended intake.

Lathyrus sativus (khesari), which constitutes a principal food crop for many in India, has been known for decades to cause neolathyrism. The causative agent, *N*-oxalyl-L-α-diaminopropionic acid (ODAP), produces partial or total loss of control of the lower limbs with associated neurological symptoms. Common methods of preparation, including soaking in lime water and boiling, are effective in destroying this amino acid.

The seeds of legumes may contain hemagglutenins and lectins that may cause destruction of the epithelia of the gastrointestinal tract; interfere with cell mitosis; cause hemorrhage; impede renal, cardiac, and hepatic function; and produce red blood cell agglutination. Many of these compounds are rendered inactive by moist heat, and the toxicity may be further reduced or neutralized by digestive enzymes, making them poorly absorbed. Because lectins reach the colon mostly in an inactive state, they appear to protect humans from colon cancer by causing hypersecretion of intestinal mucus, or by direct toxic effect on tumor cells.

Saponins disrupt red blood cells and may produce diarrhea and vomiting. They may also have a beneficial effect by complexing with cholesterol and thus lowering serum cholesterol levels. In humans, intestinal microflora seem to either destroy saponins or inactivate them in small concentrations.

Acute toxicoses resulting from consumption of toxic mushrooms is infrequent, yet of increasing concern because of the practice of gathering fungi in the wild. The most serious of these toxicoses result from the Amanita family of mushrooms which contains several toxic peptides belonging to the amatoxin and phallotoxin groups.

Both the common cultivated mushroom as well as the Shitake mushroom contain hydrazines that have been shown to be carcinogenic precursors in experimental animals. Hydrazine levels, however, vary considerably as a function of variety, processing, storage, and preparation. One week of refrigerated storage reduces levels significantly, and all hydrazines are lost during canning and/or cooking.

Phytoalexins

Phytoalexins are low molecular weight compounds produced in plants as a defense mechanism against microorganisms. They do, however, exhibit toxicity to humans and other animals in addition to microbes. Coumarins, glycoalkaloids, isocoumarins, isoflavonoids, linear furanocoumarins, stilbenes, and terpenes all fall into the category of phytoalexins. Because phytoalexins are natural components of plants, and because their concentration may increase as a response to production and management stimuli, it is useful to recognize the possible effects of phytoalexins in the human diet.

Linear furanocoumarins are potent photosensitizing agents in celery, parsley, parsnips, limes, and figs. The most commonly reported symptoms include contact dermatitis and photodermatitis, particularly on the hands and forearms.

Other common phytoalexins in food materials are pisatin, cinnamylphenols, glyceolin, phaseolin [CAS: 13401-40-6], and 5-deoxykieritol in peas, beans, soybeans, and lima beans; viniferin in grapes; momilactones and oryzalexins in rice; α-tomatine in tomato; lubimen in eggplant; and capsidiol in green peppers.

Enumerable phytoalexins, including furanosesquiterpene, ipome - amarone, eudesmanes, and others, have been isolated from mold-infected sweet potatoes. The clinical symptoms seem to revolve around lung edema. Whereas high concentrations of these chemicals can occur in damaged sweet potatoes, the occurrence is much less (by as much as 20-fold) in nondamaged sweet potatoes. Of possible concern to human health is the fact that blemishes sufficient to result in large increases in concentration of lung-edema toxins are not always easily detected by the naked eye. Additionally, these compounds are heat stable.

Oligosaccharides

Oligosaccharides, specifically the α-galactosides raffinose [CAS: 512-69-6], stachyose [CAS: 470-55-3], and verbascose [CAS: 546-62-3], are widely present in legumes and are indigestible by humans because of a lack of α-galactosidase. As a result, these compounds undergo fermentation in the colon with the concomitant production of CO_2, H_2, and CH_4, commonly referred to as flatulence. Reports have shown germination to be effective in reducing α-galactoside content of cowpeas and other legumes.

Goitrogens are compounds that produce goiter by interfering with thyroxine synthesis in the thyroid gland. Foodborne goitrogens are often characterized by the presence of sulfur and most are thiocyanates or closely related compounds. Because of their widespread occurrence in Cruciferae, eg, cabbage, kale, onions, cress, broccoli, cauliflower, rutabaga, turnip, and radish, goitrogens are among the most common and longest recognized substances of toxic nature in the human food supply. See also **Oligosaccharides**.

Oxalates, Phytates, and Other Chelates

Of nutrient chelates in the human diet, oxalates and phytates are the most common. Oxalic acid, found principally in spinach, rhubarb leaves, beet leaves, some fruits, and mushrooms, is a primary chelator of calcium. Oxalate present in pineapple, kiwifruit, and possibly in other foods, occurs as calcium oxalate [CAS: 563-72-4], CaC_2O_4. This compound is in the form of needle-like crystals, known as raphides, which can produce painful sensations in the mouth when eaten raw. The effects of oxalic acid in the diet may be twofold. First, it forms strong chelates with dietary calcium, rendering the calcium unavailable for absorption and assimilation. Secondly, absorbed oxalic acid causes assimilated Ca to be precipitated as insoluble salts that accumulate in the renal glomeruli and contribute to the formation of renal calculi.

Phytic acid, although restricted to a more narrow range of food products, mainly grains, complexes a broader spectrum of minerals than does oxalic acid. Decreased availability of P is probably the most widely recognized result of excessive intakes of phytic acid, yet Ca, Cu, Zn, Fe, and Mn are also complexed and rendered unavailable by this compound. High intakes of both calcium and vitamin D help to offset the deleterious effects of oxalates. See also **Vitamin**.

Vasoactive and Psychoactive Amines and Alkaloids

Most compounds producing hypertensive episodes are classified as amines and are found in greatest concentration in banana, plantain, tomato, avocado, pineapple, broad beans, and various cheeses. Amines that are vasoactive include dopamine [CAS: 51-61-6], $C_8H_{11}NO_2$; tyramine; histamine [CAS: 51-45-6], $C_5H_9N_3$; tryptamine [CAS: 61-54-1], $C_{10}H_{12}N_2$; noradrenaline [CAS: 51-41-2], $C_8H_{11}NO_3$; and dihydroxyphenylalanine [CAS: 59-92-7] (DOPA), $C_9H_{11}NO_4$.

Patients receiving monoamine oxidase inhibitors (MAOI) as antidepressant therapy have been especially subject to the hypertensive effects of vasoactive amines. These dietary amines have also been implicated as causative agents in migraine. Other naturally occurring alkaloids have been recognized for centuries as possessing neurological stimulant and depressant properties. See also **Alkaloids**.

Caffeine, a xanthine derivative, has been consumed for thousands of years and is present in over 60 plant species including coffee beans, tea leaves, cacao beans and cola nuts. In addition to naturally occurring sources, caffeine has been used as a food ingredient (flavoring) for over 100 years. Caffeine is rapidly and completely absorbed, being distributed quickly throughout the body with no so-called barriers to limit absorption or distribution. Compounding this rapid absorption is the fact that caffeine is inefficiently excreted by the kidneys. Caffeine produces stimulatory effects by facilitating mental and muscular effort and diminishes drowsiness and fatigue. Individual thresholds of toxicity vary considerably, but symptoms such as restlessness, increased respiration, muscular tension and twitching, and tachycardia may imply acute toxicity.

Depressant symptoms, which include burning abdominal pain, decreased excitability, convulsions, nausea, and coma, become the general syndrome for all oral alkaloid poisoning. Discorine [CAS: 3329-91-7], a γ-unsaturated lactone found in yams, is an alkaloid having the empirical formula $C_{13}H_{21}O_2N$; it has been isolated from Nigerian yams, thus establishing the discorine-type alkaloids as representative of the *Dioscorea*

genus of plants. Myristicin, found in both nutmeg and mace, is a psychoactive agent that may be fatal in infants who consume as little as two whole nutmegs. Its toxicity resemble alcohol intoxications.

Several glycoalkaloids present in food are of toxicological interest. Solanine, found in potatoes, tomatoes, apples, eggplant, and sugar beets, has been responsible for several cases of moderate to severe poisoning. Solanine is a cholinesterase inhibitor and toxic doses are probably ca 200 mg. Market potatoes contain about 1–5 mg of solanine per 100 g fresh weight. The USDA establishes solanine levels of 20 mg/100 g as the limit for safe consumption.

Antinutrients

Any substance that destroys, inactivates, or in other ways renders unavailable an essential dietary constituent can be termed an antinutrient. The most widely studied are antivitamins. The presence of antivitamins in certain foods means that merely assuring an adequate intake of a vitamin is no guarantee that a deficiency state cannot exist physiologically. The enzyme thiaminase acts by either specific splitting of the thiamine molecule or nonspecific hydrolysis. Niacin inhibitors, acting through nicotinamide mononucleotide (NMN) depression in erythrocytes, have been studied in corn and millet, and a biotin antagonist, avidin, has long been recognized in raw egg white. Linatine [CAS: 10139-06-7], found in flaxseed, is the only pyridoxine antagonist known and seems to function by the formation of a stable complex. Yeast and pea seedlings contain specific pantothenic acid antagonists, although the structure and mode of action are unexplained. Riboflavin antagonism, found only in the Akee plum of Jamaica, is rather rare, but is of interest because it can be fatal.

The antagonisms that exist between unsaturated fatty acids, and carotene and vitamin E are complicated and largely undefined. Linoleic acid acts as an antivitamin to *dl* -α-tocopherol [CAS: 59-02-9, 1406-18-9, 10191-41-0] (vitamin E) by reducing availability through direct intestinal destruction. Various lipoxidases destroy carotenes and vitamin A.

Investigations have focused on the content of polyphenolics, tannins, and related compounds in various foods and the influence on nutrient availability and protein digestibility. It has been established that naturally occurring concentrations of polyphenoloxidase and polyphenols in products such as mushrooms can result in reduced iron bioavailability. Likewise, several studies have focused on decreased protein digestibility caused by the tannins of common beans and rapeseed (canola).

Vitamin Toxicity

Reported cases of vitamin toxicity owing to overdose are usually associated with increased over-the-counter availability of supplemental vitamins and indiscriminate supplementation. Fat-soluble vitamins tend to accumulate in the body with relatively inactive mechanism for excretion and cause greater toxicological difficulties than do water-soluble vitamins.

Infants may be sensitive to doses of vitamin A [CAS: 11103-57-4] in the range of 75,000–200,000 IU (90.6–1.5 g), although the toxic dose in adults is probably 2–5 million IU (90.6–1.5 g). Intakes in this range from normal food supplies without oral supplements are simply beyond imagination. Dangerous doses of vitamin D [CAS: 1406-16-2] seem to lie in the range of 1000–3000 IU/kg body wt (25–75 μg/kg body wt). Cases of toxicity of both vitamins E and K have been reported, but under ordinary circumstances these vitamins are considered relatively innocuous.

Of the water-soluble vitamins, intakes of nicotinic acid [CAS: 59-67-6] on the order of 10 to 30 times the recommended daily allowance (RDA) have been shown to cause flushing, headache, nausea, and moderate lowering of serum cholesterol with concurrent increases in serum glucose. Toxic levels of folic acid [CAS: 59-81-7] are ca 20 mg/d in infants, and probably approach 400 mg/d in adults. The body seems able to tolerate very large intakes of ascorbic acid [CAS: 50-81-7] (vitamin C) without ill effect, but levels in excess of 9 g/d have been reported to cause increases in urinary oxalic acid excretion. Urinary and blood uric acid also rise as a result of high intakes of ascorbic acid, and these factors may increase the tendency for formation of kidney or bladder stones. All other water-soluble vitamins possess an even wider margin of safety and present no practical problem.

Essential Minerals and Heavy Trace Elements

Ingestion of at least 10 times normal levels of essential minerals would be required to approach toxic proportions. See also **Mineral Nutrients**. The only exceptions occur in cases of plant foods grown on soils unusually high in Mo [CAS: 7439-98-7], Se [CAS: 7782-49-2], and Cu [CAS: 7740-50-8]. Levels can reach toxic quantities in these cases, but these are rare occurrences.

Cases involving human toxicity from heavy trace elements, such as Pb [CAS: 7439-92-1], Hg [CAS: 7439-97-6], As [CAS: 7440-38-2], and Cd [CAS: 7440-43-9], are much more common but are almost exclusively traced to accidental contamination rather than true natural occurrences. Consumption of seafoods taken from waters where industrial pollution raised mercury levels has been responsible for some reported cases of mercury poisoning. Methylmercury acetate [CAS: 108-07-6] seems to be the toxic compound of most interest to humans and is formed primarily from microbial action. Infrequent problems with lead and cadmium have been traced to steels and equipment containing these elements coming in contact with foods during handling or processing. See also **Food Processing**. Naturally high levels of arsenic have been reported in some crustaceans and fishes, yet food problems have been restricted to meats taken from livestock treated with arsenic-containing antibiotics or to accidental contamination.

Cyanogenic Glycosides

Complex glycosides, which upon hydrolysis yield hydrogen cyanide [CAS: 74-90-8], are commonly found among plant materials. The toxicity of this class of compounds, found in the bitter almond, pits of stone fruits, sorghum, and lima beans, is directly related to HCN liberation upon digestive hydrolysis. Amygdalin, the cyanogenic glycoside of apricot pits, has been promoted as both a cancer cure and a vitamin. However, it has never been associated with a medically verified cancer cure, and no trained nutritionist recognizes the compound as a vitamin. Indeed, many cases of poisoning, and even death, have been ascribed to its use. Approximately 50 apricot pits contain a fatal dose of amygdalin.

The cyanogenic glycosides, phaseolunatin [CAS: 554-35-8], $C_{10}H_{17}NO_6$, and vicianin [CAS: 155-57-7], $C_{19}H_{25}NO_{10}$, have been isolated from lima beans and vetch, respectively. Several studies have reported that heating (cooking) acts to decrease the quantity of HCN liberated by these compounds upon enzymatic hydrolysis.

Nitrates, Nitrites, and Nitrosamines

The carcinogenicity of nitrosamines has created widespread concern over the safety of food products that are significant sources of nitrates and nitrites. Nitrosamines are readily formed by reaction of secondary amines with nitrites at acid pH, conditions which may occur in the gastrointestinal tract.

Nitrates are found in fairly high concentrations in beets, spinach, kale, collards, eggplant, celery, and lettuce. Additionally, nitrates and nitrites are commonly used in the curing solutions of bacon, ham, and other cured meats. In cured meats, nitrates and nitrites control the growth of microorganisms, particularly *Clostridium botulinum* , and also serve as color preservatives.

Although the potentially carcinogenic nitrosamines may be present in foods, particularly cured meats, occurrence is infrequent and at low levels. USDA regulations stipulate that ascorbic acid be added to cured meats at five times the level of nitrates and nitrites to prevent the formation of carcinogenic *N*-nitroso compounds. See also **Food Additives**.

Sodium Chloride

Sodium chloride [CAS: 7647-14-5] is an essential dietary component. It is necessary for proper acid–base balance and for electrolyte transfer between the intra- and extracellular spaces. The adult human requirement for NaCl probably ranges between 5–8 g/d. The normal diet provides something in excess of 10 g/d NaCl, and adding salt during cooking or at the table increases this intake.

Excessive intake of NaCl contributes to increased fluid retention, and in some individuals there may be a relationship between NaCl intake and hypertension. Few topics have caused such debate among nutritionists and physicians. There is no doubt that the relationship between hypertension and NaCl intake is of significance when compounded by obesity, or in about 30% of hypertensives. Edema resulting from excessive salt intake, especially in relatively inactive persons, is a principal contributing factor in elevated blood pressure. Both consumers and food processors have reduced use of NaCl.

Toxins

The condition produced by the consumption of moldy foods containing toxic material is referred to as mycotoxicosis. Molds and fungi fall into this category and several derive their toxicity from the production of oxalic acid, although the majority of mycotoxins are much more complex.

Mycotoxins find their way into the human diet by way of mold-contaminated cereal and legume crops, meat, and milk products. Corn and peanuts probably represent the most common sources of mycotoxins in the human diet. Many mycotoxins are acutely toxic as well as being potent carcinogens.

Many parasitic fungi have been shown to produce toxins; however, the toxins of *Aspergillus* and *Penicillium* have perhaps the greatest potency against humans.

Virtually scores of fish and shellfish species have been reported to have toxic manifestations. Most of these toxicities have been shown to be microbiological in origin. There are a few, however, that are natural components of seafoods.

Several species of the moray eel (*Gymnothorax*) have caused toxic reactions, especially in Japan. The toxic principle appears to be proteinaceous and is found predominately in the blood but it may occur in the flesh as well. Its exact structure remains somewhat uncertain.

Amnesic shellfish poisoning resulted in four deaths in northeastern Canada in the early 1990s, and domoic acid, the causative agent, was first documented on the Washington and Oregon coasts in 1991. The toxin is produced by a single-celled phytoplankton that constitutes part of the food chain of some shellfish, including Dungeness crab. Domoic acid is concentrated in the tissues of these shellfish, and upon ingestion can result in symptoms including memory loss (hence the name of the condition), and in large doses, ultimately death. Domoic acid is not affected by common methods of food preparation and no medical treatment is presently available for acute poisoning.

Pufferfish toxin, isolated from a dozen or more species, has been identified as having the empirical formula $C_{11}H_{17}N_3O_8$, but the structure is not well-established, nor is it certain that the same structure is universally responsible for poisoning, although this is assumed to be the case. The so-called paralytic shellfish poisoning reported in many areas of the world has a microbiological etiology, and is thus more accurately a contamination rather than a natural toxicosis. The paralytic effects of the poisoning begin as a tingling sensation in the lips, tongue, and extremities, and gradually progress into nausea and convulsions. Japanese statistics indicate mortality rates approaching 65%.

The liver of sharks and other oily fishes sometimes accumulate toxic levels of vitamin A, and cases of acute poisoning have been reported both among Eskimos and the Japanese.

Cyasin, a component of the nut of the cycad tree, a native of tropical environs, produces an acute toxicity in addition to drastically increasing the incidence of Lou Gerhig's disease (amyotropic lateral sclerosis). Cyasin is carcinogenic.

Estrogens are ingested by humans from both plant (cereal grains, legumes, potatoes, carrots, parsley, tree fruits, yams, vegetable oils) and animal (liver, egg yolk) sources. Whereas estrogens are known to promote tumor growth, the activity of food estrogen is one-tenth to one-thousandth the level of the most common human circulating estrogen.

A toxic component of braken fern, perhaps either quercetin or ptaquiloside, a glucoside, has a mixed history of carcinogenicity. It is sometimes implicated in an increased incidence of bladder cancer in animals and esophageal cancer in humans. Multiple other dietary components seem to either promote or interfere with its action, and the significance of braken fern in human carcinogenesis remains unproven.

Halogenated compounds, found in high concentrations in seaweeds consumed in Japan and Hawaii, have been suspected of being carcinogenic, largely based on epidemiological extrapolation (high incidences of hepatic carcinoma). However, direct human causation has not been established.

Urethane [CAS: 51-79-6] (ethyl carbamate) occurs as a natural by-product in fermented products such as wine, liquors, yogurt, beer, bread, olives, cheeses, and soy sauces. Whereas urethane has a known cancer etiology in experimental animals, no such relationship has yet been proven in humans. Alcohol may act by blocking the metabolism of urethane, and thus exert a protective effect in humans consuming alcoholic beverages.

Polycyclic aromatic hydrocarbons (PAHs) are carcinogens produced by the thermal breakdown of organic materials. These are widely distributed in both food and the environment, and are some of the principal carcinogens in cigarette tar and air pollution. Of over 20 PAHs isolated, benzopyrene and quinoline compounds are the most commonly encountered in foods, particularly those which are broiled or fried. Shellfish living in petroleum contaminated waters may also contain PAHs.

Legislation and Regulatory Considerations

There exists little specific legislation dealing with natural toxicants in foods. The *1958 Food Additives Amendment to the Federal Food, Drug, and Cosmetic Act* stipulates that no substance that has been shown to be carcinogenic to either humans or animals may be added to the food supply. Accordingly, those foods that contain added carcinogens are subject to the Delaney Clause. Maximum tolerances of heavy metals, such as Pb and Hg, have been established by FDA at 0.5 ppm in the food product. For aflatoxins, there is presently a zero tolerance in effect (based on the Delaney Clause), and screening is generally on a qualitative basis. With these exceptions, natural toxicants in food products are generally not treated by specific food legislation. Naturally occurring toxicants have been reviewed in greater detail elsewhere. See also **Foodborne Diseases**; and **Toxicology**.

FOOT-AND-MOUTH DISEASE. Foot-and-mouth disease (FMD) is a severe, highly communicable and economically devastating viral disease of cattle and swine. It also affects sheep, goats, deer, and other cloven-hoof ruminants. Many affected animals recover, but the disease leaves them debilitated. FMD causes severe losses in the production of meat and milk. The disease does not effect food safety or humans. Other susceptible species include hedgehogs, nutria, rats, armadillos, elephants, capybaras, and mice. FMD is not recognized as a zoonotic disease. The disease is characterized by fever and blisterlike lesions followed by erosions on the tongue and lips, in the mouth, on the teats, and between the hooves. Because it spreads widely and rapidly and because it has grave economic as well as clinical consequences, FMD is one of the animal diseases that livestock owner dread most.

In 350 B.C., Aristotle mentioned a cattle plague that could have been FMD or rinderpest. In 1546, the Italian physician Fracastorius gave the first clear description of the disease. For the next two centuries, the number of outbreaks in Europe increased. In 1897, Foeffler and Frosch demonstrated for the first time that FMD was caused by a filterable agent. Before the availability of an FMD vaccine, when an outbreak of the disease occurred, European farmers would deliberately spread it to other animals in the herd by rubbing the tongues of infected cattle with a rough towel and then rubbing the same towel on the tongues of healthy cattle. Farmers did this to shorten the course of the disease in their herds and provide immunity against the next outbreak of FMD. But observers noted that animals that recovered were not always protected against future outbreaks of FMD. This observation led to the demonstration in 1922 of type 0 (Oise valley) and type A (Allemagne) in France. In 1926, a third serotype was recognized and named C in anticipation that the previously recognized serotypes would be renamed to allow naming of additional serotypes, A, B, C, etc. The SAT subtypes were described between 1934 and 1948, and Asia 1 was isolated in Pakistan in 1954. The United States has experienced nine distinct epizootics; the most serious occurred in 1914, invading 22 states and the District of Columbia. The latest outbreak, which occurred in California in 1929, was quickly controlled. The United Kingdom Ministry of Agriculture, Fisheries and Food (MAFF) confirmed on February 20, 2001 an outbreak of foot and mouth disease, virus type O, in Essex County, England. The disease was confirmed on two premises in close proximity;

a slaughter plant and a nearby farm. On February 22, a third case of FMD was confirmed at a cattle farm inside the 8-kilometer exclusion zone. On February 23, MAFF confirmed two additional cases; one on a farm in Essex county, and one on a hog farm located 300 miles north of Essex. This latter farm had supplied hogs to the slaughter establishment mentioned above. The virus was confirmed as the same South East Asian strain as that found in Japan and Korea and associated with swill in South Africa. Prior to this outbreak, the UK was considered by the USDA to be free of FMD. The last outbreak of FMD in the UK was in 1981.

The FMD disease is caused by a virus. The FMD virus (FMDv) is a member of the genus *Apthovirus* in the family Picornaviridae. The virion is a small (23-nm) single-stranded RNA virus. The virus survives in lymph nodes and bone marrow at neutral pH, but destroyed in muscle when in pH<6.0 i.e. after rigor mortis. The virus can persist in contaminated fodder and the environment for up to one month, depending on the temperature and pH conditions. There are seven serotypes of FMD virus, O, A, C, Asia 1, SAT 1, SAT 2 and SAT 3, distributed throughout the world and many subtypes of the FMD virus. Immunity to one type does not protect an animal against other types.

Serotype O is the most widely distributed, being endemic in many South American, African and Asian countries, affecting all susceptible species. It has caused recent outbreaks in Italy (1993), Greece (1994 and 1996), Bulgaria (1991, 1993 and 1996), Georgia (1997), Armenia (1996) and the southern republics of the former Soviet Union, Taiwan (1997), Russia (1995), and Philippines (major outbreaks in 1996). Certain strains of serotype O appear particularly adapted to a particular host species.

Within serotype O there are groups of strains (genotypes) that are associated with particular areas of distribution, and species preference. The Middle East type O is well adapted to sheep and cattle (possibly due to the small number of pigs in the region), whereas the Far East type O is responsible for the major outbreaks in pigs in that region. In areas where there are outbreaks in pigs and cattle (e.g., Vietnam), the strains causing disease in each species are easily distinguishable by nucleotide sequencing.

Serotype A is present in South America, Africa and Asia, and in 1996 caused outbreaks in Albania, the former Yugoslav Republic of Macedonia and Serbia, following the introduction of infected meat products. It is characterised by local outbreaks which appear self-limiting, even though the strains of serotype A causing the outbreak may be outside the protection provided by available vaccine strains. The antigenic diversity of strains of serotype A is much greater than that seen within the other serotypes.

Four antigenically new strains of serotype A have been identified during 1996 and 1997 in Iran, Malaysia, Thailand, Eritrea and West Africa. The new serotype A strain in Iran spread into Turkey during 1997 and threatened to enter Europe through Turkish Thrace.

Serotype C is found in South America, Africa and Asia. It is characterised by sporadic outbreaks and subsequent disappearance from an area for a variable time. In recent years, only in the Philippines has it been associated with a continuous series of outbreaks since its introduction there in 1976. However, there have been no recorded outbreaks in the Philippines due to type C since 1995.

Serotype Asia 1. The Asia 1 serotype is restricted to the Middle and Far East. It rarely causes outbreaks in pigs, and is mainly seen in the cattle and Asian buffalo populations. This serotype has been found circulating in association with serotype O and/or serotype A, and its presence in diagnostic samples may be missed.

SAT Serotypes (South African Territories). The SAT viruses are restricted to Africa, although they have caused occasional outbreaks in the Middle East which have never persisted. The SAT 1 and SAT 3 serotypes rarely cause outbreaks in cattle and are usually only found in the African buffalo populations. The SAT 2 serotype is the most frequently found cause of FMD in cattle in sub-Saharan Africa. It can maintain itself for many years, particularly in the zebu breed of cattle. Other wildlife species, particularly impala, have been implicated in the transmission of SAT serotypes between buffalo and cattle.

The FMD viruses can be spread by animals, people, or materials that bring the virus into physical contact with susceptible animals. An outbreak can occur when:

- People wearing contaminated clothes or footwear or using contaminated equipment pass the virus to susceptible animals.
- Animals carrying the virus are introduced into susceptible herds.
- Contaminated facilities are used to hold susceptible animals.
- Contaminated vehicles are used to move susceptible animals.
- Raw or improperly cooked garbage containing infected meat or animal products is fed to susceptible animals.
- Susceptible animals are exposed to materials such as hay, feedstuffs, hides, or biologics contaminated with the virus.
- Susceptible animals drink common source contaminated water.
- A susceptible cow is inseminated by semen from an infected bull.

Once an animal becomes infected, the primary mode of spread is then via respiratory aerosols. Other important means of spread are direct and indirect contact. In an outbreak of FMD, the three primary hosts transmit the disease as follows:

- Sheep act as maintenance hosts.
- Pigs act as amplifiers.
- Cattle act as indicators.

When sheep or goats become infected with FMDv, the disease may not be diagnosed for a considerable time because signs and lesions can be very mild. During this time, however, the animals will be producing infectious aerosols, contaminating fomites, and spreading the virus by contact. FMD in pigs spreads very rapidly because pigs produce 30 to100 times as much virus in aerosols as do sheep or cattle. An infected pig can produce a hundred million infectious doses per day.

When cattle are infected with FMDv, signs and lesions usually develop more rapidly and are more severe than lesions in pigs, sheep, or goats. If cattle, sheep, and pigs are exposed together, cattle will usually get sick first. Possibly, cattle are subject to increased exposure due to their greater pulmonary tidal volume.

Some strains of FMDv seem to affect particular species more than other strains. For example, some strains affect pigs but not cattle. In South America, mature cattle have had clinical signs of FMD while sheep in an adjacent pasture were normal.

Vesicles (blisters) followed by erosions in the mouth or on the feet and the resulting excessive salivating or lameness are the best known signs of the disease. Often blisters may not be observed because they easily rupture, leading to erosions.

Some of these other signs may appear in affected animals during an FMD outbreak:

- Temperatures rise markedly, then usually fall in about 2 to 3 days.
- Ruptured vesicles discharge either clear or cloudy fluid and leave raw, eroded areas surrounded by ragged fragments of loose tissue.
- Sticky, foamy, stringy saliva is produced.
- Consumption of feed is reduced because of painful tongue and mouth lesions.
- Lameness with reluctance to move is often observed.
- Abortions often occur.
- Milk flow of infected cows drops abruptly.
- Conception rates may be low.

Meat animals do not normally regain lost weight for many months. Recovered cows seldom produce milk at their former rates. FMD can lead to myocarditis (inflammation of the muscular walls of the heart) and death, especially in newborn animals.

FMD can be confused with several similar, but less harmful, diseases, such as vesicular stomatitis, bluetongue, bovine viral diarrhea, and foot rot in cattle, vesicular exanthema of swine, and swine vesicular disease. Whenever mouth or feet blisters or other typical signs are observed and reported, laboratory tests must be completed to determine whether the disease causing them is FMD.

While the disease is widespread around the world, North America, Central America, Australia, New Zealand, Chile, and some countries in Europe are considered free of FMD. Various types of FMD virus have been identified in Africa, South America, Asia, and part of Europe.

FMD is one of the most difficult animal infections to control. Because the disease occurs in many parts of the world, there is always a chance of its accidental introduction into the United States. Animals and animal byproducts from areas known to be infected are prohibited entry into the United States.

Livestock animals in the United States are highly susceptible to FMD viruses. If an outbreak occurred in the United States, this disease could spread rapidly to all sections of the country by routine livestock movements unless it was detected early and eradicated immediately.

If FMD were to spread unchecked, the economic impact could reach billions of dollars in the first year. Deer and wildlife populations could become infected rapidly and could be a source for re-infection of livestock.

FOOT-CANDLE. A unit of illuminance or illumination equal to one lumen per square foot. This is the illuminance provided by a light source of luminous intensity one candela (formerly candle) at a distance of 1 ft, hence the name. Full sunlight with zenith sun produces an illuminance of about 10 000 foot-candles on a horizontal surface. Full moonlight provides an illuminance of about 0.02 foot-candles. Adequate illumination for reading is taken to be about 10 foot-candles; that for machine shop work is about 40 foot-candles.

See also **Lux**.

FOOTING. A footing is a foundation structure used to distribute wall or column loads to the bearing soil or to the piling. There are two general classifications of column footings. The isolated spread footing (see Fig. 1) supports one column, and the combined footing supports two. Footings must be spread wider than the base of a column or wall for a number of reasons. They must give stability by reducing the unit pressure below that at which there might be local settlement along one side of the foundation. They must be thick enough to resist the punching shear of the column, and they must not flare so rapidly as to cause them to be weak in bending. Footing for walls, columns, etc. may be very conveniently and economically made of reinforced concrete. Except for very heavy loads, the footing slab is usually square or rectangular and of constant thickness. Design is usually made by semirational rules and formulae since the distribution of stress in such a structural unit is very complex. For very heavy column loads the footing is usually made in the form of a truncated pyramid or preferably in a series of steps giving the "stepped footing." The latter type, illustrated in Fig. 1, predominates, due to the ease with which forms may be constructed. In case the soil is so weak as to require an extremely wide footing, a steel I-beam grillage is incorporated in the footing.

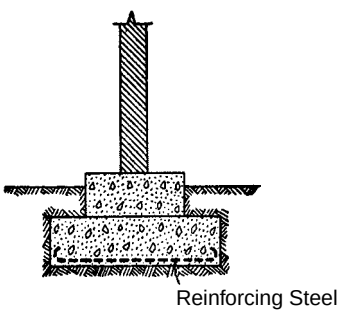

Fig. 1. Sectional view of spread footing.

FOOT (Physiology). 1. The ventral protuberance of the body of a mollusk, usually an organ of locomotion.

2. The terminal portion of a jointed appendage, which comes into contact with the supporting surface. In quadrupedal vertebrates the term is applied to both fore and hind appendages and in bipedal forms to the latter only.

The Human Foot. With the increased interest in personal athletics, in walking and running for fitness, much more attention has been given to exercising correctly and in selecting proper foot protection. Scores of shoe designs have appeared worldwide during the last few years. Finding the right shoe begins with a determination of foot type, if not already known. As shown by Fig. 1, there are three fundamental foot types. It is helpful to learn the nomenclature that applies to shoes (i.e., the outsole, midsole, and insole, the toe box, and the heel counter). Much can be learned from an examination of old shoes that have provided a lot of use. If the heel counter leans in, a shoe with good stability and motion control is indicated.

Fig. 1. Wet prints of three principal types of the human foot: (**a**) normal foot, for which the largest variety of shoes is available; (**b**) high-arched or rigid foot, showing unconnected areas (heel and forefoot) in the footprint (this type of foot requires a shoe with maximum cushion and no motion control); (**c**) flat foot, where the complete footprint shows, with a wide band connecting the heel and the forefoot. The proper shoe for a flat foot must provide good stability and motion control.

It if leans out, a new shoe that has good cushion, allowing the foot ample mobility, is indicated. The midsole should be checked for loss of shock absorbency. Generally, a running shoe should be checked for wear after about 200 miles (320 km). Where guidance is not available from the shoe supplier, injury prevention guidance can be obtained from an experienced orthopaedist, physical therapist, biomechanist, or podiatrist, most of whom are knowledgeable in gait patterns and running problems.

Excellent information is also obtainable from some of the periodicals, such as *Runner's World*, which specialize in this field and where annually a shoe terminology and buyer's guide is featured.

This brief summary was suggested by the *Hughston Health Alert*, issued by the Hughston Sports Medicine Foundation, Inc., Columbus, Georgia 31995.

FORAMEN. An opening, especially in bone, through which other structures pass, such as nerves and blood vessels.

FORBES, EDWARD (1815–1854). Edward Forbes was the son of a banker and a native of the Isle of Man, where as a youth he acquired a passion for the study of marine invertebrates. He attended the University of Edinburgh (1831–1836) as first a medical and later an arts student, but took no degree. Fascinated by questions of the spatial and temporal distribution of species, Forbes's early reports on the geographical distribution and depth zonation of invertebrates resulted in British Association sponsorship of a Dredging Committee which he led from 1839 till the 1850s. During explorations in the Aegean Sea as naturalist aboard HMS *Beacon* (1841–1842) Forbes concluded that marine life dwindled to zero beyond 300 fathoms. The reality and extent of this "azoic zone" later became a significant stimulus for Britain's subsequent oceanographic efforts; during the expedition of HMS *Challenger* (1872–1876) the notion was finally debunked.

In addition to monographs on marine invertebrates *British Starfishes*, 1841; *Naked-eyed Medusae*, 1848; and *British Mollusca*, 4 Vols. 1848–1853), Forbes published a controversial essay in *Geological Survey Memoirs* (1846) on the historical origins of the British flora and fauna and their migrations from the Continent and Atlantic islands. He readily hypothesized fluctuating land bridges over which terrestrial species might pass –an important, and later much criticized (e.g. by Darwin) device in historical biogeography. See also **Biogeography (The History)**.

Forbes held the posts of Professor of Botany, King's College London (1843–1854) and Paleontologist to the Geological Survey of Great Britain (1844–1854). In the latter capacity he helped work out the stratigraphy of the (Jurassic) Purbeck Beds of Dorset. In 1854 he succeeded Robert Jameson as Regius Professor of Natural History at Edinburgh, but he died of kidney disease before the year was out, at the age of 39. His final work, published posthumously by Robert Godwin-Austen, was the

biogeographic synthesis *Natural History of the European Seas* (1859). Forbes was one of the most congenial naturalists of his era, taking great pleasure in organizing, and composing light satirical poetry for scientific social events. His literary efforts were collected posthumously as *Literary Papers* (1855). See also **Paleontology (The History)**.

FORBIDDEN LINE. A line in a spectrum resulting from a transition from a metastable state within an atom. Forbidden lines are not found in ordinary sources, but may be conspicuous in very large bodies of rarefied gas where the time interval between collisions of atoms is long. Forbidden lines of oxygen appear, for example, in the aurora.

FORBUSH DECREASE. The observed decrease in cosmic ray activity in the Earth's atmosphere about a day after a solar flare. The Forbush decrease is believed to be caused by a shielding effect of the magnetic fields contained in the plasma cloud emitted from the sun at the time of the flare.

FORCE. Three general uses of the term force are:

1. In dynamics, the physical agent that causes a change of momentum, measured by the time rate of change of momentum. If the speeds involved are low compared with that of light, a force may be defined as proportional to the mass m of a body and to the acceleration a of the body which is produced by the force. Thus $\mathbf{f} = km\mathbf{a}$, where k is a constant for a given system of units, and has the dimensionless value unity in length-mass-time systems or 1/g in length-force-time systems, g being the acceleration due to gravity. Force is a vector quantity, requiring both a magnitude and a direction for its complete specification.

2. In statics, the physical agent that produces an elastic strain in a body. Static forces are equated to dynamic forces by the method of allowing a weight to produce a strain and then by allowing the same weight to fall under the action of gravity.

3. From its initial conception, which was purely mechanical as expressed in (1) and (2), above, the term force extends to denote loosely any operating agency, such as coercive force, electromotive force, and magnetomotive force.

Furthermore, there are a number of compound terms denoting various special forces:

An *impressed force* is any external force acting on a particle in a dynamical system. The resultant force on each such particle can always be resolved into a resultant external impressed force and a resultant internal constraint force. Thus in the case of a particle suspended by a string, the weight is the impressed force and the tension in the string is the constraint force.

A *restoring force* is the elastic force, which acts on a particle or portion of a mechanical system when displaced from equilibrium. Its direction is such as to return the system to equilibrium. In simple cases, the restoring force is linear, i.e., proportional to the first power of the distance. For some physical systems, however, the restoring force may be proportional to the second or higher power of the distance.

A *tangential force* is a force associated with a wheel or disk always acting perpendicular to the radius, e.g., frictional force between a rolling wheel and a surface, or frictional force between a belt and a pulley wheel.

An *attractive force* is a force acting on a particle such that the acceleration of the particle is in the direction of the agency responsible for the force. This agency can be another single particle, a collection of particles or a region acting as the source of a field.

Concurrent forces are a system of forces such that there exists a single point common to all the lines of action of the forces.

Coplanar forces are a system of forces such that the lines of action of all the forces lie in a single plane.

Parallel forces are a system of forces such that the lines of action of all the forces are parallel to each other.

FORCE-BALANCE TRANSDUCER. A transducer in which the output from the sensing member is amplified and fed back to an element which causes the force-summing member to return to its rest position.

There are scores of examples of where force-balance transducers are applied in industrial measurements. The use of a force-balance transmitter to measure a liquid level in a pressurized tank is shown in Fig. 1. As the head of liquid varies, the pressure on one side of the differential pressure sensor bellows changes. This pressure is rapidly equalized by instrument air, and the greater or lesser pressure required is registered by the pressure gage, calibrated in this case in units of liquid level.

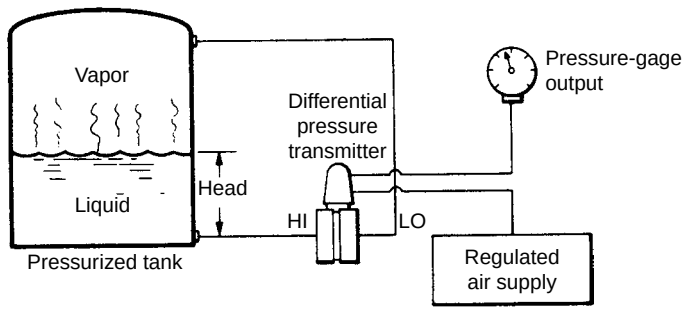

Fig. 1. Force-balance transmitter used in level measurement of liquid in a pressurized tank.

FORENSIC CHEMISTRY. Forensic chemistry can be defined as the application of chemistry to the law. In American jurisprudence, courts, and judges are established to make factual determinations of matters brought before them. The fact-finding of the courts must often grapple with complex scientific issues and the legal system [Giannelli, P. C.] has a particular way to deal with these technical and scientific matters. The court calls on subject matter experts [Hodgkinson, T.], ie, expert witnesses, to explain and to interpret for the triers of fact the meaning of the scientific concept underlying a case and how it may be interpreted. To testify as an expert witness in a particular field or area of endeavor, the individual must qualify as an expert in a specific area, ie, have special knowledge, skill, training experience, or education. Courts have used subject matter experts for generations [Moenssens, et. al.]. The judge sitting on the particular case makes the determination whether an individual is qualified to give expert testimony.

Forensic science is an applied science having a focus on practical scientific issues that come up during criminal investigations or at trial. Some components are unique to the field because it is conducted within the legal arena. Forensic science issues in chemistry and biochemistry in criminal investigations are discussed herein. There are a host of other forensic science areas, eg, forensic medicine, forensic dentistry, forensic anthropology, forensic psychiatry, and forensic engineering, any of which may overlap with forensic chemistry.

Physical Evidence

Forensic scientists work with physical evidence, i.e., "data presented to a court or jury in proof of the facts in issue and which may include the testimony of witnesses, records, documents or objects." Physical evidence is real or tangible and can literally include almost anything, e.g., the transient scent of perfume on the clothing of an assault victim; the

metabolite of a drug detected in the urine of an individual in a driving-under-the-influence-of-drugs case; the scene of an explosion; or bullets removed from a murder victim's body.

Examination of physical evidence provides two subtle and different types of conclusion. All members of a class or group have identical characteristics. Types of physical evidence which exhibit class characteristics are paint, glass, fibers, fabric, building material, etc. This type of physical evidence is said to be identified. The best that chemical and physical examinations can ever do is to place items into groups of similarly manufactured items. It is not possible to differentiate one item of evidence as being uniquely distinguishable from another.

Some types of physical evidence, because of the manner in which the material is made, are unique; such evidence can be individualized. Examination can show an item of individualized evidence is unique and comes from one, and only one source. The classic example is fingerprints. Other categories of evidence exhibiting individualization are handwriting, markings on bullets fired from the same gun, broken pieces of glass or plastic which can be physically fit together again, and forensic deoxyribonucleic acid (DNA) evidence.

Historically, physical evidence has taken on increasing importance in criminal matters. Courts have often looked askance at a defendant's admissions of guilt and even on occasion questioned eyewitness testimony. Physical evidence has traditionally been viewed as impartial and unbiased, and not subject to the problems associated with confessions made by an accused or the testimony of witnesses.

Physical evidence serves three purposes. In some cases it is used to prove a component or element of a crime. For example, in a case involving trafficking in cocaine [CAS: 50-36-2], the prosecutor must prove that the white powder found in the criminal's possession was cocaine. The forensic chemist tests the substance and issues a report. If the powder is methamphetamine [CAS: 537-46-2], the charge must be amended.

Physical evidence is also used is to develop associative evidence in a case. Physical evidence may help to prove a victim or suspect was at a specific location, or that the two came in contact with one another.

Finally, physical evidence may be used to reconstruct the events that took place during the commission of a crime. For example, at the scene of a multiple murder bloodtyping of dried bloodstains found in various rooms indicated that two of the victim's bodies had been moved from where they had been attacked. The movement of the bodies was part of an attempt on the part of the murderer to make it appear that the victims had been killed by intruders.

Most of the forensic science or crime laboratories located in North America are associated with law enforcement agencies, medical examiner–coroner departments, or prosecutors' offices. There are a small number of private laboratories that provide forensic testing in specialized areas such a DNA profiling, forensic toxicology and fire debris analysis. There are a large number of independent consultants, also. Laboratories exist at the municipal, county, state, and federal levels of government. There are ~300 government-operated forensic science laboratories in the United States. Many of the government-operated and private forensic science laboratories are now accredited by the American Society of Crime Laboratory Directors–Laboratory Accreditation Board (ASCD–LAB).

Forensic science laboratories are generally divided into separate specialty areas. These typically include forensic toxicology, solid-dose drug testing, forensic serology, trace evidence analysis, firearms and tool mark examination, questioned documents examination, and latent fingerprint examination. Laboratories principally employ chemists, biochemists, and biologists at various degree levels. In some specialty areas, eg, firearms examination, questioned documents, and fingerprint examination, experts may not have an academic degree. Some laboratories employ examiners that specialize only in one area, whereas other laboratories maintain a generalist philosophy, rotating examiners through several forensic science disciplines during a practitioner's career. The generalist approach has become difficult to impliment as more and more specialized education is required for one to become a forensic analyst or examiner in certain areas. For example, under the educational guidelines of the DNA Advisory Board DNA analysts are expected to have had college level course work in biochemistry, molecular biology, and genetics. Forensic analysts and examiners may be certified by organizations such as the American Board of Criminalistics. Certification generally requires passing a general knowledge examination about forensic science.

The bulk of the scientific testing in crime laboratories involves the analysis and characterization of either synthetic or biochemical organic substances or both. Additionally there are a number of evidence categories classified as inorganic. Most assays are simply qualitative and designed to answer the questions: what is it, where did it come from, and could it have come from a specific source? Quantitative analyses may also be carried out on samples involving drug evidence, toxicology evidence, and blood alcohol testing, wherever such information has probative value to the investigation or to the court in its deliberation.

Forensic Testing

Substances. Psychoactive substances, illicit and ethical (licit) drugs and alcohol (ethanol), are the greatest source of physical evidence analyzed in most crime laboratories. Drug testing falls into two categories: solid dose samples and toxicology related cases, e.g., blood, urine, or tissue specimens in post-mortem cases or cases involving driving under the influence of alcohol or drugs, as well as workplace or employee drug testing.

The number of driving under the influence of alcohol (DUI) cases reflects the enormity of the drunken driving problem in the United States. Tests to measure blood alcohol concentration are conducted on blood, urine, or breath [Mason and Dubowski]. In the case of urine and breath, the alcohol concentration measured is reported in terms of the equivalent blood alcohol concentration. Most states in the United States presume that a person is under the influence of alcohol with respect to driving a motor vehicle at a blood alcohol concentration of 0.10%, ie, an ethanol concentration of 10 g/100 mL of blood. Some states have set a lower concentration of 0.08%. In some European countries levels are as low as 0.05%. A blood alcohol concentration of 0.10% in a 68-kg (150-lb) person is the equivalent to the alcohol in about four drinks of 80 proof alcoholic beverage or four 340-g (12-oz) beers (see Beer; Beverage spirits, distilled; Wine). Ethanol is metabolized at a rate equivalent to about one drink per hour [Jones].

Blood and urine are most often analyzed for alcohol by headspace gas chromatography using an internal standard, e.g., 1-propanol. Assays are straightforward and lend themselves to automation. Urine samples are collected as a voided specimen, ie, subjects must void their bladders, wait ~20 min, and then provide the urine sample. Voided urine samples provide the most accurate determination of blood alcohol concentrations. Voided urine alcohol concentrations are divided by a factor of 1.3 to determine the equivalent blood alcohol concentration. The 1.3 value is used because urine contains one-third more water than blood and, at equilibrium, there is about one-third more alcohol in the urine as in the blood.

Breath alcohol testing is accomplished by a number of techniques. The oldest reliable procedure involves bubbling a measured volume of deep-lung air containing alcohol through an acidic solution of potassium dichromate, $K_2Cr_2O_7$. Deep-lung air is the last portion of expired breath. It is collected in breath alcohol testing to ensure that the alcohol concentration in the breath is in equilibrium with the alcohol in the alveolar blood supply. Newer instruments rely on infrared spectroscopy to measure the blood alcohol concentration in breath.

Driving under the influence of alcohol cases are complicated because people sometimes consume alcohol with other substances. The most common illicit substances taken with alcohol are marijuana and cocaine. In combination with alcohol, some drugs have an additive effect. When a blood or urine sample is tested for alcohol and the result is well below the legal concentration threshold yet the arresting officers observed that the subject was stuporous, further toxicological tests for the possible presence of drugs are indicated.

Forensic toxicology laboratories having large caseloads rely on immunoassay techniques to screen specimens. Immunoassay technology involves the manufacture of antibodies that are specific to particular drugs or to a class of drugs. For example, morphine (Table 1) can be chemically bound to a protein and injected into a host animal, such as a goat. After several weeks the animal is bled and antibodies for morphine and related drugs can be isolated and purified.

There are several immunological techniques in use. Enzyme multiplied immunological technique (EMIT) employs an enzymatic reaction to determine concentration, whereas radioimmunoassay (RIA) uses radioactively tagged reagents such as ^{125}I to measure concentration.
